September 1998

Abstract
We present a novel algorithm to compute large itemsets online. The user is free
to change the support threshold any time during the first scan of the transaction
sequence. The algorithm maintains a superset of all large itemsets and for each
itemset a shrinking, deterministic interval on its support. After at most 2 scans the
algorithm terminates with the precise support for each large itemset. Typically our
algorithm is by an order of magnitude more memory efficient than Apriori or DIC.¹

¹An earlier version of this report appeared as Technical Report UCB//CSD-98-1004, Department
of Electrical Engineering and Computer Science, University of California at Berkeley.
1 Introduction

Mining for association rules is a form of data mining introduced in [AIS93]. The prototypical example is based on a list of purchases in a store. An association rule for this list is a rule such as “85% of all customers who buy product A and B also buy product C and D”. Discovering such customer buying patterns is useful for customer segmentation, cross-marketing, catalog design and product placement.

We give a problem description which follows [BMUT97]. The support of an itemset (set of items) in a transaction sequence is the fraction of all transactions containing the itemset. An itemset is called large if its support is greater or equal to a user-specified support threshold, otherwise it is called small. An association rule is an expression $X \Rightarrow Y$ where $X$ and $Y$ are disjoint itemsets. The support of this rule is the support of $X \cup Y$. The confidence of this rule is the fraction of all transactions containing $X$ that also contain $Y$, i.e. the support of $X \cup Y$ divided by the support of $X$. In the example above, the “85%” is the confidence of the rule \{A, B\} $\Rightarrow$ \{C, D\}. For an association rule to hold, it must have a support $\geq$ a user-specified support threshold and a confidence $\geq$ a user-specified confidence threshold. Existing algorithms proceed in 2 steps to compute association rules:

1. Find all large itemsets.
2. For each large itemset $Z$, find all subsets $X$, such that the confidence of $X \Rightarrow Z \setminus X$ is greater or equal to the confidence threshold.

We address the first step, since the second step can already be computed online, c.f. [AY97]. Existing large itemset computation algorithms have an offline or batch behaviour: given the user-specified support threshold, the transaction sequence is scanned and rescanned, often several times, and eventually all large itemsets are produced. However, the user does not know, in general, an appropriate support threshold in advance. An inappropriate choice yields, after a long wait, either too many or too few large itemsets, which often results in useless or misleading association rules.

Inspired by online aggregation, c.f. [Hel96, HHW97], our goal is to overcome these difficulties by bringing large itemset computation online. We consider an algorithm to be online if: 1) it gives continuous feedback, 2) it is user controllable during processing and 3) it yields a deterministic and accurate result. Random sampling algorithms produce results which hold with some probability $< 1$. Thus we do not view them as being online.

In order to bring large itemset computation online, we introduce a novel algorithm called Carma (Continuous Association Rule Mining Algorithm). The algorithm needs, at most, two scans of the transaction sequence to produce all large itemsets.

During the first scan, the algorithm continuously constructs a lattice of all potentially large itemsets (large with respect to the scanned part of the transaction sequence). For each set in the lattice, Carma provides a deterministic lower and upper
bound for its support. We continuously display, e.g., after each transaction processed, the resulting association rules to the user along with bounds on each rule's support and confidence. The user is free to adjust the support and confidence thresholds at any time. Adjusting the support threshold may result in an increased threshold for which the algorithm guarantees to include all large itemsets in the lattice. If satisfied with the rules and bounds produced so far, the user can stop the rule mining early.

During the second scan, the algorithm determines the precise support of each set in the lattice and continuously removes all small itemsets.

Existing algorithms need to rescan the transaction sequence before any output is produced. Thus, they cannot be used on a stream of transactions read from a network for example. In contrast, using Carma's first-scan algorithm, we can continuously process a stream of transactions and generate the resulting association rules online, not requiring a rescan.

While not being faster in general, Carma outperforms Apriori and DIC on low support thresholds and is up to 60 times more memory efficient.

2 Overview

The paper is structured as follows: In Section 3, we put our algorithm in the context of related work. In Section 4, we give a sketch of Carma. It uses two distinct algorithms PhaseI and PhaseII for the first and second scan respectively. In Section 5 we describe PhaseI in detail. In Subsection 5.1 we introduce support lattices and support sequences, the building blocks for the PhaseI algorithm presented in Subsection 5.2. We illustrate PhaseI on an example in Subsection 5.3. We discuss changing support thresholds in Subsection 5.4. After a short description of PhaseII in Subsection 6.1, we combine in Subsection 6.2 PhaseI with PhaseII, yielding Carma. In Section 7 we discuss our implementation. After a brief discussion of implementational details in Subsection 7.1, we compare in Subsection 7.2 the performance of Carma with Apriori and DIC. In Subsection 7.3 we analyze how the support intervals evolve during the first scan. We end with our conclusion in Section 8. In Appendix A we summarize performance results of Apriori, Carma and DIC on further datasets. In Appendix B we further discuss our theoretical bounds on the support intervals. In Appendix C we give a formal proof of correctness for PhaseI. In Appendix D we introduce a forward pruning technique for PhaseII and prove its correctness.

3 Related Work

Most large itemset computation algorithms are related to the Apriori algorithm due to Agrawal & Srikant, c.f. [AS94]. See [AY98] for a survey of large itemset computation algorithms. Apriori exploits the observation that all subsets of a large itemset are large themselves. It is a multi-pass algorithm, where in the $k$-th pass all large itemsets
of cardinality $k$ are computed. Hence Apriori needs up to $c + 1$ scans of the database where $c$ is the maximal cardinality of a large itemset.

In [SON95] a 2-pass algorithm called Partition is introduced. The general idea is to partition the database into blocks such that each block fits into main-memory. In the first pass, each block is loaded into memory and all large itemsets, with respect to that block, are computed using Apriori. Merging all resulting sets of large itemsets then yields a superset of all large itemsets. In the second pass, the actual support of each set in the superset is computed. After removing all small itemsets, Partition produces the set of all large itemsets.

In contrast to Apriori, the DIC (Dynamic Itemset Counting) algorithm counts itemsets of different cardinality simultaneously, c.f. [BMUT97]. The transaction sequence is partitioned into blocks. The itemsets are stored in a lattice which is initialized by all singleton sets. While a block is scanned, the count (number of occurrences) of each itemset in the lattice is adjusted. After a block is processed, an itemset is added to the lattice if and only if all its subsets are potentially large, i.e. large with respect to the part of the transaction sequence for which its count was maintained. At the end of the sequence, the algorithm rewinds to the beginning. It terminates when the count of each itemset in the lattice is determined. Thus after a finite number of scans, the lattice contains a superset of all large itemsets and their counts. For suitable block sizes, DIC requires fewer scans than Apriori.

We note that all of the above algorithms: 1) require that the user specifies a fixed support threshold in advance, 2) do not give any feedback to the user while they are running and 3) may need more than two scans (except Partition). Carma, in contrast: 1) allows the user to change the support threshold at any time, 2) gives continuous feedback and 3) requires at most two scans of the transaction sequence.

Random sampling algorithms have been suggested as well, c.f. [Toi96, ZPLO96]. The general idea is to take a random sample of suitable size from the transaction sequence and compute the large itemsets using Apriori or Partition with respect to that sample. For each itemset, an interval is computed such that the support lies within the interval with probability $\geq$ some threshold. Carma, in contrast, deterministically computes all large itemsets along with the precise support for each itemset.

Several algorithms based on Apriori were proposed to update a previously computed set of large itemsets due to insertion or deletion of transactions, c.f. [CHNW96, CLK97, TBAR97]. These algorithms require a rescan of the full transaction sequence whenever an itemset becomes large due to an insertion. Carma, in contrast, requires a rescan only if the user needs the precise support of the additional large itemsets, instead of the continuously shrinking support intervals provided by Phase I.

In [AY97] an Online Analytical Processing (OLAP)-style algorithm is proposed to compute association rules. The general idea is to precompute all large itemsets relative to some support threshold $s$ using a traditional algorithm. The association rules are then generated online relative to an interactively specified confidence threshold and support threshold $\geq s$. We note that: 1) the support threshold $s$ must be
specified before the precomputation of the large itemsets, 2) the large itemset computation remains offline and 3) only rules with support \( \geq s \) can be generated. Carma overcomes these difficulties by bringing the large itemset computation itself online. Thus, combining Carma’s large itemset computation with the online rule generation suggested in [AY97] brings both steps online, not requiring any precomputation.

4 Sketch of the Algorithm

Carma uses distinct algorithms, called PhaseI and PhaseII, for the first and second scan of the transaction sequence. In this section, we give a sketch of both algorithms. For a detailed description and formal definition see Section 5 and Section 6.

During the first scan PhaseI continuously constructs a lattice of all potentially large itemsets. After each transaction, it inserts and/or removes some itemsets from the lattice. For each itemset \( v \), PhaseI stores the following three integers (see Figure 1 below, the itemset \( \{a, b\} \) was inserted in the lattice while reading the \( j \)-th transaction, the current transaction index is \( i \):

\[
\begin{align*}
\text{count}(v) & \quad \text{the number of occurrences of } v \text{ since } v \text{ was inserted in the lattice.} \\
\text{firstTrans}(v) & \quad \text{the index of the transaction at which } v \text{ was inserted in the lattice.} \\
\text{maxMissed}(v) & \quad \text{upper bound on the number of occurrences of } v \text{ before } v \text{ was inserted in the lattice.}
\end{align*}
\]

Suppose we are reading transaction \( i \) and we have a lattice of the above form. For any itemset \( v \) in the lattice, we then have a deterministic lower bound \( \text{count}(v)/i \) and upper bound \( (\text{maxMissed}(v) + \text{count}(v))/i \) on the support of \( v \) in the first \( i \) transactions. We denote these bounds by \( \text{minSupport}(v) \) and \( \text{maxSupport}(v) \) respectively. The computation of \( \text{maxMissed}(v) \) during the insertion of \( v \) in the lattice is a central part of the algorithm. It not only depends on \( v \) and \( i \), the current transaction index, but also on the current and previous support thresholds, since the user may change the threshold at any time.

After PhaseI has read a transaction, it increments \( \text{count}(v) \) for all itemsets \( v \) contained in the transaction. Next, it inserts some itemsets in the lattice, computing \( \text{maxMissed} \) and setting \( \text{firstTrans} \) to the current transaction index. Clearly,
**maxMissed** is always less than the current transaction index. Eventually, PhaseI may remove some itemsets from the lattice if their **maxSupport** is below the current support threshold. At the end of the transaction sequence, PhaseI guarantees that the lattice contains a superset of all large itemsets relative to some threshold. The threshold depends on how the user changed the support during the scan, c.f. Subsection 5.4. We then rewind to the beginning and start PhaseII.

PhaseII initially removes all itemsets which are trivially small, i.e. itemsets with **maxSupport** below the last user specified threshold. By rescanning the transaction sequence, PhaseII determines the precise number of occurrences of each remaining itemset and continuously removes all itemsets, which turn out to be small. Eventually, we end up with the set of all large itemsets along with their supports.

### 5 PhaseI Algorithm

In this section, we fully describe the PhaseI algorithm, which constructs a superset of all large itemsets while scanning the transaction sequence once. In Subsection 5.1 we introduce **support lattices** and **support sequences**, the building blocks for PhaseI. We present the PhaseI algorithm itself in Subsection 5.2. We illustrate the algorithm on an example in Subsection 5.3 and conclude this section with a discussion of changing support thresholds in Subsection 5.4.

#### 5.1 Support Lattice & Support Sequence

For a given transaction sequence and an itemset \( v \), we denote by \( \text{support}_i(v) \) the support of \( v \) in the first \( i \) transactions. Let \( V \) be a lattice of itemsets such that for each itemset \( v \in V \) we have the three associated integers \( \text{count}(v) \), \( \text{firstTrans}(v) \) and \( \text{maxMissed}(v) \) as defined in Section 4. We call \( V \) a **support lattice** (up to \( i \) and relative to the support threshold \( s \)) if and only if \( V \) contains all itemsets \( v \) with \( \text{support}_i(v) \geq s \). Hence, a support lattice is a superset of all large itemsets.

![Graph](image-url)

**Figure 2**

For each transaction processed, the user is free to specify an arbitrary support threshold. Thus we get a sequence of support thresholds \( \sigma = (\sigma_1, \sigma_2, \ldots) \), where \( \sigma_i \) denotes the support threshold for the \( i \)-th transaction. We call \( \sigma \) a **support sequence**. By \( [\sigma]_i \) we denote the least monotone decreasing sequence which is up to \( i \) pointwise greater or equal to \( \sigma \) and 0 otherwise (see Figure 2 below). We call \( [\sigma]_i \) the **ceiling**
of \( \sigma \) up to \( i \). By \( \text{avg}_i(\sigma) \) we denote the running average of \( \sigma \) up to \( i \), i.e. \( \text{avg}_i(\sigma) = \frac{1}{i} \sum_{j=1}^{i} \sigma_j \). We note that \([\sigma]_{i+1}\) can readily be computed from \([\sigma]_i\) and \(\sigma_{i+1}\), c.f. Lemma 2 in Appendix C.

### 5.2 PhaseI Algorithm

In this subsection, we give a full description and formal definition of the PhaseI algorithm. PhaseI computes a support lattice \( V \) as it scans the transaction sequence. We define \( V \) recursively:

Initially PhaseI sets \( V \) to \( \{\emptyset\} \) with \( \text{count}(\emptyset) = 0 \), \( \text{firstTrans}(\emptyset) = 0 \) and \( \text{maxMissed}(\emptyset) = 0 \). Thus \( V \) is a support lattice for the empty transaction sequence.

Let \( V \) be a support lattice up to transaction \( i-1 \). We read the \( i \)-th transaction \( t_i \) and want to transform \( V \) into a support lattice up to \( i \). Let \( \sigma_i \) be the current user-specified support threshold. To maintain the lattice we proceed in three steps: 1) **increment** the count of all itemsets occurring in the current transaction, 2) **insert** some itemsets in the lattice and 3) **prune** some itemsets from the lattice.

1) **Increment:** We increment \( \text{count}(v) \) for all itemsets \( v \in V \) that are contained in \( t_i \), maintaining the correctness of all integers stored in \( V \).

2) **Insert:** We insert a subset \( v \) of \( t_i \) in \( V \) if and only if all subsets \( w \) of \( v \) are already contained in \( V \) and are potentially large, i.e. \( \text{maxSupport}(w) \geq \sigma_i \). This corresponds to the observation that the set of all large itemsets is closed under subsets. Inserting \( v \) in \( V \), we set \( \text{firstTrans}(v) = i \) and \( \text{count}(v) = 1 \), since \( v \) is contained in the current transaction \( t_i \). Since \( \text{support}_i(w) \geq \text{support}_i(v) \) for all subsets \( w \) of \( v \) and \( w \subset t_i \) we get

\[
\text{maxMissed}(v) \leq \text{maxMissed}(w) + \text{count}(w) - 1.
\]

By the following Theorem 1 we have

\[
\text{support}_{i-1}(v) > \text{avg}_{i-1}(\lceil \sigma \rceil_{i-1}) + \frac{|v|-1}{i-1} \quad \text{implies} \quad v \in V.
\]

Since \( v \) is not contained in \( V \) yet, we get thereby

\[
\text{support}_{i-1}(v) \leq \text{avg}_{i-1}(\lceil \sigma \rceil_{i-1}) + \frac{|v|-1}{i-1}.
\]  

(1)

Since \( \text{maxMissed}(v) \) is an integer\(^2\) we get by inequality (1)

\[
\text{maxMissed}(v) \leq \lceil (i-1)\text{avg}_{i-1}(\lceil \sigma \rceil_{i-1}) \rceil + |v| - 1.
\]

Thus we define \( \text{maxMissed}(v) \) as

\[
\min \{ \lceil (i-1)\text{avg}_{i-1}(\lceil \sigma \rceil_{i-1}) \rceil + |v| - 1, \\
\text{maxMissed}(w) + \text{count}(w) - 1 \mid w \subset v \}.
\]  

(2)

In particular we get \( \text{maxMissed}(v) \leq i - 1 \), since the emptyset is a subset of \( v \), \( \emptyset \) is an element of \( V \) and the count of \( \emptyset \) equals \( i \), the current transaction index.

\(^2\)For a real number \( x \) we denote by \( \lfloor x \rfloor \) the largest integer less or equal to \( x \), i.e. \( \lfloor x \rfloor = \max \{ i \in \mathbb{Z} \mid x \geq i \} \).
3) Prune: We prune the lattice by removing all itemsets of cardinality ≥ 2 with a maxSupport below the current support threshold σ, i.e. all small itemsets containing at least 2 items. Since pruning incurs a considerable overhead we only prune every \([1/σ_i]\) or every 500 transactions\(^3\), whichever is larger. We note that any heuristic pruning strategy is admissible as long as only small itemsets are removed and whenever an itemset is removed all its supersets are removed as well. We chose the above pruning strategy for its memory efficiency. Note that in this strategy 1-itemsets are never pruned. Thus an item, which is not contained in the lattice, did not appear in the transaction sequence so far. Hence the strategy allows us to set maxMissed to 0 whenever a 1-itemset is inserted in the lattice.

The resulting PhaseI algorithm is depicted in figure 3.

Function PhaseI( transaction sequence \((t_1, \ldots, t_n)\), support sequence \(σ = (σ_1, \ldots, σ_n)\) : support lattice; support lattice \(V\);
begin
\(V := \{\emptyset\}, \text{maxMissed}(v) := 0, \text{firstTrans}(v) := 0 \text{ count}(v) := 0.\)
for \(i\) from 1 to \(n\) do
  // 1) Increment
  for all \(v \in V\) with \(v \subseteq t_i\) do \(\text{count}(v) += \); od;
  // 2) Insert
  for all \(v \subseteq t_i\) with \(v \notin V\) do
    if \(∀w \subseteq v : w \in V\) and \(\text{maxSupport}(w) ≥ σ_i\) then
      \(V := V \cup \{v\};\)
      \(\text{firstTrans}(v) := i;\)
      \(\text{count}(v) := 1;\)
      \(\text{maxMissed}(v) := \text{min}\{ [(i - 1) \text{avg}_{i-1}(|σ_{i-1}|)] + |v| - 1,\)
      \(\text{maxMissed}(w) + \text{count}(w) - 1 |w \subseteq v \} ;\)
      if \(|v| = 1\) then \(\text{maxMissed}(v) := 0;\) fi;
    fi;
  od;
  // 3) Prune
  if ( \(i \% \text{max}\{\lfloor 1/σ_i \rfloor, 500\} \) == 0 then
    \(V := \{v \in V \mid \text{maxSupport}(v) ≥ σ_i\) or \(|v| = 1\}\};\)
  fi;
od;
return \(V\);
end;

The correctness of the algorithm is given by the following theorem:

\(^3\)For a real number \(x\) we denote by \(\lfloor x \rfloor\) the least integer greater or equal to \(x\), i.e. \(\lfloor x \rfloor = \min\{i \in \mathbb{Z} \mid x ≤ i\}\).
**Theorem 1** Let \( V \) be the lattice returned by PhaseI\( (T, \sigma) \) for a transaction sequence \( T \) of length \( n \) and support sequence \( \sigma \).

Then \( V \) is a support lattice relative to the support threshold

\[
\text{avg}_{\sigma}([\sigma]_n) + \frac{c + 1}{n}
\]

with \( c \) the maximal cardinality of a large itemset in \( T \). For any itemset \( v \)

\[
\text{support}_{\sigma}(v) > \text{avg}_{\sigma}([\sigma]_n) + \frac{|v| - 1}{n}
\]

implies \( v \in V \).

Proof: By double induction on \( c \) and \( n \). For a detailed proof see Theorem 2 in Appendix C.

We illustrate Theorem 1 and in particular the support threshold given by (3) in Subsection 5.4. We omitted any optimization in the definition of PhaseI. For example, the incrementation and insertion step can be accomplished by traversing the support lattice once. We illustrate the algorithm itself on a simple example in the following Subsection 5.3.

### 5.3 Example

We illustrate in this subsection the PhaseI algorithm on a simple example, namely on the transaction sequence \( T = (\{a, b\}, \{a, b, c\}, \{b, c\}) \) and the support sequence \( \sigma = (0.3, 0.9, 0.7) \), see Figure 4 below. As indicated we denote by the triple the three associated integers for each set in the support lattice \( V \) and by the interval the bounds on its support.

We initialize \( V \) to \( \{\emptyset\} \) and the associated integers of \( \emptyset \) to \((0,0,0)\).

![Figure 4](image-url)

Reading \( t_1 = \{a, b\} \) we first increment the \( \text{count} \) of \( \emptyset \), since \( \emptyset \subseteq t_1 \). Because the empty set is the only strict subset of a singleton set and \( 1 = \max \text{Support}(\emptyset) \geq \sigma_1 \), we add
the singletons \{a\} and \{b\} to V. By \textit{maxMissed} = 0 for all singleton sets, we set their associated integers to \((0, 1, 1)\). Since there is no set in V with \textit{maxSupport} < 0.3, we can not prune an itemset from V and the first transaction is processed.

Reading \(t_2 = \{a, b, c\}\) we first increment \textit{count} for \(\emptyset\), \{a\} and \{b\}. As above we insert the singleton set \{c\}, setting \textit{maxMissed} to 0. Since \{a, b\} \subseteq t_2 and \{a\}, \{b\} are elements of V with a \textit{maxSupport} \geq \sigma_2 = 0.9, we insert \{a, b\} in V. Since \([\sigma]_1 = (0.3, 0, 0, \ldots)\) we get \(\text{avg}_1([\sigma]_1) = 0.3\) and

\[
\frac{[(2 - 1)\text{avg}_1([\sigma]_1)] + 2 - 1}{1} = 1.
\]

Hence \textit{maxMissed}(\{a, b\}) = 1 by equality (2) of Subsection 5.2, since \textit{maxMissed}(w) + \textit{count}(w) = 2 for \(w = \{a\}\) and \(w = \{b\}\). We set the associated integers of \{a, b\} to \((1, 2, 1)\). We note that \textit{maxSupport}(\{a, b\}) = 1 is a sharp upper bound, since \textit{support}_2(\{a, b\}) = 1.

Reading \(t_3 = \{b, c\}\) we increment the count of \(\emptyset\), \{b\} and \{c\}. We then insert \{b, c\} since \{b\} and \{c\} are elements of V with \textit{maxSupport} above the new user defined support threshold \(\sigma_3 = 0.5\). By \([\sigma]_2 = (0.9, 0.9, 0, 0, \ldots)\) we get \(\text{avg}_2([\sigma]_2) = 0.9\) and hence \(\frac{[(3 - 1)\cdot 0.9] + 2 - 1}{1} = 2.\) Since \textit{maxMissed}(\{c\}) + \textit{count}(\{c\}) + 1 \{c\} we get

\[
\text{maxMissed}(\{b, c\}) = \min\{2, 1\} = 1.
\]

Because all itemsets have a \textit{maxSupport} greater than 0.5 we can not remove any itemsets from the lattice. If \(\sigma_3\) was 0.7 instead of 0.5 we would not have inserted \{b, c\} while we could have removed \{a, b\}. However we could not have removed \{c\}, since our pruning strategy during \textit{Phase I} never removes singleton sets.

### 5.4 Changing Support Thresholds

We discuss in this subsection constant and changing support thresholds. \textit{Phase I} guarantees that all itemset with a support greater or equal to the support threshold given by Theorem 1 are included in the itemset lattice. We denote by the \textit{guaranteed support threshold} this threshold, i.e.

\[
\text{avg}_n([\sigma]_n) + \frac{c + 1}{n} \quad (4)
\]

with \(\sigma\) the support sequence, \(c\) the maximal cardinality of a large itemset and \(n\) the current transaction index.

First, suppose the user does not change the support threshold. Hence we have a constant support sequence \(\sigma = (s, s, s, \ldots)\) for some \(s\). By (4) and \(\text{avg}_n([\sigma]_n) = s\) \textit{Phase I} includes at transaction \(n\) all large itemsets with a support \(\geq s + \frac{c + 1}{n}\). Thus, the guaranteed threshold \(s + \frac{c + 1}{n}\) converges to the user specified support threshold \(s\) as \textit{Phase I} scans the transaction sequence. To improve the speed of convergence, we run \textit{Phase I} with a lower threshold of \(s \cdot 0.9\) instead of \(s\). As the guaranteed threshold reaches \(s\), we increase the threshold again from \(s \cdot 0.9\) to \(s\), see Figure 5.
Next, consider changing support thresholds. Figure 6 depicts a scenario, where the user increases at transaction 5'000 the initial support threshold of 0.75% to 1.25% and then lowers it again to 1.0% at transaction 10'000. As above, we supply PhaseI with thresholds $\sigma_i$ lower than the user specified threshold, whenever the guaranteed threshold does not equal the user specified threshold. We set $\sigma_i$, the support sequence supplied to Carma, to $0.9 \cdot 0.75\% = 0.68\%$ for $i = 1, \ldots, 4'999$. The guaranteed threshold (4) drops quickly to 1% at transaction 4'999. Since the new user specified threshold of 1.25% at transaction 5'000 is greater than 1%, we have equality until transaction 9'999. Hence we set $\sigma_i$ to 1.25% for $i = 5'000, \ldots, 9'999$. As the user lowers the threshold to 1% we set $\sigma_i$ to $0.9 \cdot 1\% = 0.9\%$ from $i = 10'000$ until the guaranteed threshold reaches 1.0% at transaction 35’000. We reset $\sigma_i$ to 1% for all $i > 35'000$, since the user defined threshold remains at 1% from now on.

We note that the guaranteed threshold is an upper bound and thus a worst-case threshold. Typically, all large itemsets are contained in the lattice well before the guaranteed threshold reaches the user specified threshold.

6 Carma

In Subsection 6.1 we give a short description of PhaseII, the algorithm for the second scan. We then combine in Subsection 6.2 PhaseI with PhaseI, yielding Carma.

6.1 PhaseII

Let $V$ be the support lattice computed by PhaseI and let $\sigma_n$ be the user specified support threshold for the last transaction read during the first scan. PhaseII prunes all small itemsets from $V$ and determines the precise support for all remaining itemsets.

\footnote{For this example we assumed that all large itemsets or of cardinality 10 or less, i.e. $c = 10$.}
Initially PhaseII removes all trivially small itemsets, i.e. itemsets with \( \text{maxSupport} < \sigma_n \), from \( V \). Scanning the transaction sequence, PhaseII increments \( \text{count} \) and decrements \( \text{maxMissed} \) for each itemset contained in the current transaction, up to the transaction at which the itemset was inserted. Setting \( \text{maxMissed} \) to 0 we get \( \text{minSupport} = \text{maxSupport} \), the actual support of the itemset. We remove the itemset if it is small. Setting \( \text{maxMissed}(v) = 0 \) for an itemset \( v \) may yield \( \text{maxSupport}(w) > \text{maxSupport}(v) \) for some superset \( w \) of \( v \). Thus we set \( \text{maxMissed}(w) = \text{count}(v) - \text{count}(w) \) for all supersets \( w \) of \( v \) with

\[ \text{maxSupport}(w) > \text{maxSupport}(v). \]

PhaseII terminates as soon as the current transaction index is past \( \text{firstTrans} \) for all itemsets in the lattice. The resulting lattice contains all large itemsets along with the precise support for each itemset. The algorithm is shown in figure 7. Using Theorem 1 it is possible to determine that some itemset with \( \text{maxSupport} > \sigma_n \) is small before we reach its \( \text{firstTrans} \) transaction. Pruning these itemsets and all their supersets speeds up PhaseII by reducing the lattice size as well as the part of the transaction sequence which needs to be rescanned, c.f. Appendix D.

Function PhaseII( support lattice \( V \), transaction sequence \( (t_1, \ldots, t_n) \), support sequence \( \sigma \) ) : support lattice;

integer \( ft, i = 0; \)
begin
\( V := V \setminus \{ v \in V \mid \text{maxSupport}(v) < \sigma_n \}; \)
while \( \exists v \in V : i < \text{firstTrans}(v) \) do
\( i++; \)
for all \( v \in V \) do
\( ft := \text{firstTrans}(v); \)
if \( v \subseteq t_i \) and \( ft < i \) then \( \text{count}(v)++; \text{maxMissed}(v)--; \text{fi}; \)
if \( ft == i \) then
\( \text{maxMissed}(v) := 0; \)
for all \( w \in V : v \subseteq w \) and \( \text{maxSupport}(w) > \text{maxSupport}(v) \) do
\( \text{maxMissed}(w) := \text{count}(v) - \text{count}(w); \)
\( \text{od}; \)
\( \text{fi}; \)
if \( \text{maxSupport}(v) < \sigma_n \) then \( V := V \setminus \{ v \}; \text{fi}; \)
\( \text{od}; \text{od}; \)
return \( V; \)
end;

\( \text{Figure 7} \)

6.2 Carma

Executing PhaseII after PhaseI, we get Carma, c.f. Figure 8. By Theorem 1 PhaseI produces a superset of all large itemsets with respect to the guaranteed threshold.
PhaseII removes an itemset from the superset if and only if it is small. Thus the resulting itemset contains all large itemsets.

Function Carma( transaction sequence $T$, support sequence $\sigma$ ) : 
support lattice $V$;
begin
  $V := \text{PhaseI}( T, \sigma );$
  $V := \text{PhaseII}( V, T, \sigma );$
  return $V$;
end;

Figure 8

7 Implementation

To assess the performance we tested Carma along with Apriori and DIC on synthetic data generated by the IBM test data generator, c.f. [AS94] ¹. We illustrate our findings on the synthetic dataset with 100'000 transactions of an average size of 10 items chosen from 10'000 items and an average large itemset size of 4 (T10.I4.100K with 10k items). For runs on further datasets see Appendix A. All experiments were performed on a lightly loaded 300 MHz Pentium-II PC with 384 MB of RAM. The algorithms were implemented in Java on top of the same itemset lattice implementation. We cross compiled the Java class files to an executable using Tower Technology’s TowerJ 2.2.

7.1 Implementation Details

Our implementation of an itemset lattice differs from a hashtree in that all itemsets are stored in a single hashtable. With the itemsets as keys, we can quickly access any subset of a given itemset. This is important for Carma, since whenever Carma inserts a new itemset $v$, it accesses all its maximal subsets to compute $\maxMissed(v)$. We represent the lattice structure by associating to each itemset the set of all further items appearing in any of its supersets, c.f. [Bay98]. As in the case of a hashtree, we need only one hashtable access to pass from an itemset to one of its minimal supersets. Thus we can enumerate all subsets of a scanned transaction, which are contained in the lattice, as quickly as in a hashtree.

Our implementation of Carma diverges from the pseudo-code given in Subsection 5.2 only in that we perform the PhaseI incrementation and insertion step simultaneously, enumerating the subsets of a scanned transaction once.

Apriori and DIC were implemented as described in [AS94] and [BMUT97] respectively. For DIC we chose a blocksize of 15000, which we found to be fastest.

¹http://www.almaden.ibm.com/cs/quest/syndata.html
7.2 Relative Performance

To compare Carma with Apriori and DIC we ran all three algorithms on a range of datasets and (constant) support thresholds. In this subsection we illustrate our results on the T10.I4.100K dataset with 10K items. For support thresholds of 0.5% and above Apriori outperformed Carma and DIC. We attribute the superior speed of Apriori for these thresholds to the observation that, for example, at 0.75% only 171 large itemsets existed and all large itemsets were 1-itemsets. Thus Apriori completes in 2 scans allocating only 300 2-itemsets.

![Figure 9: Memory on T10.I4.100K (10K items)](image)

![Figure 10: CPU time on T10.I4.100K (10K items)](image)

As the support threshold was lowered to 0.25% (0.1%) the number of large 1-itemsets increased to 1131 (3509) and the maximal cardinality to 4 (9). We were not able to run Apriori (DIC) with thresholds below 0.2% (0.25%), since the allocated itemsets did not fit into main memory anymore. At 0.15% (0.1%) Apriori would have allocated 2.8 million (6.2 million) 2-itemsets\(^2\), while Carma required only 51001 (97872) itemsets. We note that DIC always allocates at least as many itemsets as Apriori. At 0.25% and below Carma outperformed Apriori and DIC. We attribute the better performance of Carma over Apriori to the 4 scans needed by Apriori while Carma completed in 1.1 scans. We attribute the better performance of Carma over DIC to the 2 scans needed by DIC as well as to the 35 times smaller lattice maintained by Carma, since both algorithms traverse their lattices in regular intervals.

\(^2\)The number of candidate 2-itemsets which Apriori allocates is given by the number of large 1-itemsets over 2.
7.3 Support Intervals

PhaseI maintains a superset of the large itemsets in the scanned part of the transaction sequence, but not necessarily a superset for the full transaction sequence. First, we wanted to determine the percentage of all large itemsets, i.e. with respect to the full transaction sequence, contained in the lattice as PhaseI proceeds. After scanning 20000 (40000) transactions at a threshold of 0.1% Carma included 99.3% (99.8%) of all large itemsets in its lattice, see figure 11.

![Graph showing percentage of large itemsets in lattice over transaction count.](image1)

![Graph showing size of support intervals over transaction count.](image2)

Figure 11³

Figure 12³

Between two pruning steps PhaseI replaced up to 50% of all itemsets. The vast majority (typically > 95%) of itemsets in the lattice eventually turned out to be small. As we scan the transaction sequence we would present a large number of association rules to the user based on itemsets which are likely to be small. To exclude those itemsets from the rule generation, which are likely to be small, we filtered out all itemsets which were inserted during the last 15% of the transaction sequence, e.g. at transaction 20000 we filter out all itemsets which were inserted at transaction 17000 or later. The filtered lattice still contained 93.9% (97.8%) of all large itemsets, after scanning 20000 (40000) transactions respectively, c.f. figure 9. At the same time the size of the filtered lattice was reduced to 32.6% (16.0%) of its original size.

Recall that the support interval of an itemset in the lattice is given by its \textit{minSupport} and \textit{maxSupport}. Next, we wanted to determine how the size of the support intervals, i.e. \textit{maxSupport} – \textit{minSupport}, in the filtered lattice evolve as PhaseI proceeds. After scanning 20000 (40000) transactions at a threshold of 0.1% the average interval size in the filtered lattice was 0.042% (0.032%), while 50% of all itemsets in the lattice had an interval size below 0.004% (0.002%), c.f. figure 12.

³computed on T10.I4.100K with 10K items at a support threshold of 0.1%
8 Conclusion

We presented Carma, a novel algorithm to compute large itemsets online. It continuously produces large itemsets along with a shrinking support interval for each itemset. It allows the user to change the support threshold anytime during the first scan and always completes in at most 2 scans.

We implemented Carma and compared it to Apriori and DIC. While not being faster in general, Carma outperforms Apriori and DIC on low support thresholds. We attributed this to the observation that Carma is typically an order of magnitude more memory efficient. We showed that Carma’s itemset lattice quickly approximates a superset of all large itemsets while the sizes of the corresponding support intervals shrink rapidly. We also showed that Carma readily computes large itemsets in cases which are intractable for Apriori or DIC.

An interesting feature of the algorithm is that the second scan is not needed, whenever the shrinking support intervals suffice. Thus PhaseI can be used to continuously compute large itemsets from a transaction sequence read from a network, generalizing incremental updates and not requiring local storage.

Acknowledgement: I would like to thank Joseph M. Hellerstein, UC Berkeley, for his inspiration, guidance and support. I am thankful to Ron Avnur for the many discussions and to Retus Sgier, for his help and suggestions. I would like to thank Rajeev Motwani, Stanford University, for pointing out the applicability of Carma to transaction sequences read from a network. Also, I would like to thank Ramakrishnan Srikant, IBM Almaden Research Center, for his remarks on speeding up the convergence of the support thresholds.
A Performance Figures
B Changing Support Thresholds

In this section we discuss the threshold given by Theorem 1, i.e. the support threshold for which Phasel guarantees to include all large itemsets.

Let $V$ be the support lattice constructed by PhaseI after the $i$-th transaction on a given transaction sequence and support sequence $\sigma = (\sigma_1, \sigma_2, \ldots)$. By Theorem 1 the support lattice $V$ is a superset of all large itemsets relative to the the support threshold

$$\rho_i = \text{avg}_i([\sigma],i) + \frac{c + 1}{i}$$

where $c$ is the maximal cardinality of a large itemset. If the user changed the support threshold, then $\rho_i$ can be greater than $\sigma_i$, the current user-specified threshold. In this subsection, we discuss the relationship between $\rho_i$ and $\sigma_i$. In particular:

1. The term $\frac{c + 1}{i}$ is desirable.
2. The term $\text{avg}_i([\sigma],i)$ is a sharp lower bound relative to which $V$ is a support lattice.
3. $\rho_i \rightarrow \sigma_i$ for $i \rightarrow \infty$ in typical scenarios.

1) The term $\frac{c + 1}{i}$ is desirable: Suppose $\rho_i = \text{avg}_i([\sigma],i)$ would hold instead of (5). Hence we get $\rho_1 = \sigma_1$ for the first transaction. Every subset of $t_1$ must be contained in $V$ after the first transaction $t_1$ is processed, since every subset of $t_1$ has support 1 in the initial transaction sequence $(t_1)$. If $t_1$ consist of 30 items, $V$ must contain all $2^{30}$ subsets, which is clearly not desirable. Thus the term $\frac{c + 1}{i}$ protects the support lattice constructed by PhaseI from an exponential blow-up during the first few transactions processed.

2) The term $\text{avg}_i([\sigma],i)$ is a sharp lower bound relative to which $V$ is a support lattice. Let $\sigma$ be an arbitrary support sequence. Since $[\sigma]_i$ is greater or equal to $\sigma_i$ up to $i$, we get $\text{avg}_i([\sigma],i) \geq \sigma_i$ and hence $\rho_i \geq \sigma_i$. While $V$ is a superset of all large itemsets relative to the support threshold $\rho_i$ it is not guaranteed to be a superset with respect to $\sigma_i$. By the following example we show that $\rho_i$ is a sharp lower bound on the support threshold for which $V$ is a support lattice. Let $T = (t_1, \ldots, t_{100})$ and $\sigma = (\sigma_1, \ldots, \sigma_{100})$ with

$$t_j = \begin{cases} \{ \{a\} \text{ for } j = 1, \ldots, 25 \} & \text{and } \sigma_j = \begin{cases} 0.1 & \text{for } j = 1, \ldots, 30 \\ 0.5 & \text{for } j = 31, \ldots, 51 \\ 0.0 & \text{for } j = 52, \ldots, 100 \end{cases} \\
\{ \{b\} \text{ for } j = 26, \ldots, 100 \} \end{cases}$$

Hence

$$\text{avg}_{100}(\sigma_{100}) = 0.25 + \epsilon > 0.0 = \sigma_{100}$$

with $\epsilon = 0.005$. Since $\text{support}_{51}(\{a\}) < 0.5 = \sigma_{51}$ the algorithm is free to remove $\{a\}$ from $V$ while processing transaction 51. Suppose $\{a\}$ is removed from $V$. Since $\{a\}$ is not contained in any transaction after dropping $\{a\}$ from $V$, the algorithm gets no
indication to reinclude \{a\} in V. Hence \(a \notin V\) and therefore

\[
\text{avgtool}[\sigma_{100}] = 0.25 + \epsilon > 0.25 = \text{support}_{100}(\{a\})
\]

is a sharp lower lower (by adapting the above example we can make \(\epsilon\) arbitrarily small).

3) \(\rho_i \to \sigma_i\) for \(i \to \infty\) in typical scenarios: We envision as a typical scenario, that
the user initially changes the support threshold often, in reaction to the continuously
generated association rules. After the user has found a satisfactory threshold we do
not expect further changes in the support threshold, i.e. \(\sigma_j = \sigma_{j+1} = \ldots\) for some
transaction index \(j\). Hence

\[
\rho_i \to \sigma_i \quad \text{for } i \to \infty.
\]

C Proof of Correctness for PhaseI

In this section we give a proof for the correctness of the PhaseI algorithm.

For convenience, we introduce the following conventions: Let \(I\) and \(K\) be some
sets. By \(K \subseteq I\) we denote set inclusion and by \(K \subset I\) strict set inclusion, i.e. \(K \subset I\)
if and only if \(K \subseteq I\) and \(K \neq I\). By \(I \setminus K\) we denote set exclusion, i.e. the set \(\{x \in I \mid x \notin K\}\). By \(\mathbb{N}\) we denote the natural numbers including 0 and by \(\mathbb{Z}\) the integers.

For a real number \(x\) we denote by \(\lceil x \rceil\) the least integer greater or equal to \(x\), i.e. \(\lceil x \rceil = \min\{i \in \mathbb{Z} \mid x \leq i\}\) and by \(\lfloor x \rfloor\) the largest integer less or equal to \(x\), i.e. \(\lfloor x \rfloor = \max\{i \in \mathbb{Z} \mid x \geq i\}\). Let \(V_i\) for some \(i \in \mathbb{N}\) be a sublattice of the subset lattice of \(I\). For \(t \subseteq I\) let

\[
\text{subsets}_i(t) := \{v \in V_i \mid v \subseteq t\} \quad \text{and} \quad \text{supersets}_i(t) := \{v \in V_i \mid t \subseteq v\}.
\]

Note that \(t\) itself is neither contained in \(\text{subsets}_i(t)\) nor in \(\text{supersets}_i(t)\).

To facilitate the proof we state in the following definition the PhaseI algorithm in
its recursive form:

**Definition 1** Let \(T = (t_1, t_2, \ldots)\) be a transaction sequence relative to some set \(I\)
and let \(\sigma = (\sigma_1, \sigma_2, \ldots)\) be a support sequence. We define a sublattice \(V_i\) of the subset
lattice of \(I\) and functions \(\maxMissed_i, \text{firstTrans}_i : V_i \to \mathbb{N}\) and \(\text{count}_i\) by induction
on \(i\):

Let \(i = 0\): Let \(V_0 = \{\emptyset\}, \maxMissed_0(\emptyset) = 0, \text{firstTrans}_0(\emptyset) = 0\) and \(\text{count}_0(\emptyset) = 0\).

Let \(i > 0\) and suppose we have defined \(V_j\) for all \(j < i\):

For all \(v \in V_{i-1}\) let

\[
\maxMissed_i(v) = \maxMissed_{i-1}(v), \quad \text{firstTrans}_i(v) = \text{firstTrans}_{i-1}(v)
\]

and

\[
\text{count}_i(v) = \begin{cases} 
\text{count}_{i-1}(v) & \text{if } v \notin t_i \\
\text{count}_{i-1}(v) + 1 & \text{if } v \subseteq t_i
\end{cases}
\]

Let

\[
C_i = \{v \subseteq t_i \mid v \notin V_{i-1} \text{ and } \forall w \subset v : w \in V_{i-1}, \maxSupport_i(w) \geq \sigma_i\}
\]

and
\[ D_i \subseteq \{ v \in V_{i-1} \mid \text{maxSupport}_i(v) < \sigma_i \} \]

such that if \( v \in D_i \) then \( \text{supersets}_{i-1}(v) \subseteq D_i \).

Let \( V_i = (V_{i-1} \cup C_i) \setminus D_i \). For \( v \in V_i \setminus V_{i-1} \) let

\[
\text{maxMissed}_i(v) = \min \{ (i-1) \cdot \text{avg}_{i-1}(\lfloor \sigma \rfloor_{i-1}) + |v| - 1, \]
\[
\text{maxMissed}_{i-1}(w) + \text{count}_{i-1}(w) \mid w \in \text{subsets}_{i-1}(v) \},
\]

\( \text{count}_i(v) = 1 \) and firstTrans\(_i(v) = i \).

First, we assert the correctness of our recursive definition of PhaseI:

**Lemma 1** Let \( T \) be a transaction sequence of length \( n \) and \( \sigma \) a support sequence. Let \( V \) be the lattice computed by PhaseI\((T, \sigma)\) and define \( V_n \) as in Definition 1. Define \( D_i \) in Definition 1 according to the pruning strategy chosen for PhaseI.

Then \( V = V_n \) and for each \( v \in V \) the corresponding associated integers are equal, i.e. \( \text{maxMissed}(v) = \text{maxMissed}_n(v) \), firstTrans\(_v = \text{firstTrans}_n(v) \) and count\(_v = \text{count}_n(v) \).

Proof: By induction on \( n \).

By the following lemma we can easily compute ceilings of a support sequence.

**Lemma 2** Let \( \sigma = (\sigma_1, \sigma_2, \ldots) \) be a support sequence. Then

\[ [\sigma]_{1,1} = \sigma_1 \quad \text{and} \quad [\sigma]_{1,j} = 0 \quad \text{for} \quad j \geq 2. \]

and for \( i > 1 \) we have

\[ [\sigma]_{i,j} = \begin{cases} [\sigma]_{i-1,j} & \text{for} \ j < i \ \text{and} \ [\sigma]_{i-1,j} > \sigma_i \\ \sigma_i & \text{for} \ j \leq i \ \text{and} \ [\sigma]_{i-1,j} \leq \sigma_i \\ 0 & \text{for} \ j > i \end{cases} \]

Proof: By induction on \( i \) and the definition of support ceilings.

We summarize some observations on ceilings:

**Lemma 3** Let \( \sigma = (\sigma_1, \sigma_2, \ldots) \) be a support sequence and \( i \) a positive integer. Then

1. \([\sigma]_{i+1,j} \geq [\sigma]_{i,j}\) for all \( j \),
2. \( \text{avg}_{j}([\sigma]_{i}) \geq \sigma_j \) for all \( j \leq i \),
3. \( \text{avg}_{j}([\sigma]_{i}) \geq \text{avg}_{j}([\sigma]_{j}) \) for all \( j \leq i \),

Proof: By Lemma 2.

For a transaction sequence \( T \) and an itemset \( v \) we denote by \( \text{count}_T(v) \) the number of occurrences of \( v \) in the first \( i \) transactions of \( T \).
Lemma 4 Let $T$ be a transaction sequence, $\sigma$ a support sequence and $i$ an integer. Define $V_i$ relative to $T$ and $\sigma$ as in Definition 1. Let $v \in V_i$. Then
\[ \text{count}_i(v) = \text{count}T_i(v) - \text{count}T_{\text{firstTrans}(v)}(v) \]
and $v \subseteq t_{\text{firstTrans}(v)}$.

Proof: By induction on $i$.

Lemma 5 Let $T$ be a transaction sequence, $\sigma$ a support sequence and $i$ an integer. Define $V_i$ relative to $T$ and $\sigma$ as in Definition 1. Let $v, w \in V_i$ and $w \subseteq v$. Then
\[ \maxMissed_i(w) \leq \maxMissed_i(v), \]
\[ \text{firstTrans}_i(w) \leq \text{firstTrans}_i(v), \]
\[ \text{count}_i(w) \geq \text{count}_i(v), \]
\[ \maxMissed_i(w) + \text{count}_i(w) \geq \maxMissed_i(v) + \text{count}_i(v). \]

Proof: By Definition 1 and induction on $i$.

Lemma 6 Let $T$ be a transaction sequence, $\sigma$ a support sequence and $i$ an integer. Define $V_i$ relative to $T$ and $\sigma$ as in Definition 1. Suppose $v \in V_i$ and $w \subseteq v$. Then $w \in V_i$.

Proof: Let $T = (t_1, t_2, \ldots)$ be a transaction sequence and $\sigma = (\sigma_1, \sigma_2, \ldots)$ a support sequence. Let $v \in V_i$ and $w \subseteq v$. We may assume, without loss of generality, that $w \subseteq v$. We prove Lemma 6 by induction on $i$.

Let $i = 0$. Hence $v = \emptyset = w$. Thus Lemma 6 holds trivially.

Let $i \geq 1$ and suppose Lemma 6 holds for all $V_j$ with $j < i$.

1) Suppose $v \in V_{i-1}$. Hence $w \in V_{i-1}$ by the induction hypothesis. Since $v \in V_i$ we have $v \notin D_i$. Thus $w$ is also not in $D_i$ because otherwise $v \in \text{supersets}_{i-1}(w) \subseteq D_i$, in contradiction to $v \in V_i$. Therefore $w \in V_i$.

2) Suppose $v \notin V_{i-1}$ and $w \in V_{i-1}$. By $v \in V_i$ we have $v \subseteq t_i$ and $v \in C_i$. Since $w \subseteq v$ we have $w \in \text{subsets}_{i-1}(v)$ and therefore $\maxSupport_i(w) \geq \sigma_i$ since $v \in C_i$. Thus $w \notin D_i$ and since $w \in V_{i-1}$ we have $w \in V_i$.

3) Suppose $v \notin V_{i-1}$ and $w \notin V_{i-1}$. By $v \in V_i$ we have $v \subseteq t_i$ and $v \in C_i$. Since $w \subseteq v$ we get $w \in V_{i-1}$ by Definition 1, in contradiction to $w \notin V_{i-1}$. Hence this case does not occur.

Lemma 7 Let $T$ be a transaction sequence, $\sigma$ a support sequence and $i$ an integer. Define $V_i$ relative to $T$ and $\sigma$ as in Definition 1. Then $\emptyset \in V_i$, $\maxMissed_i(\emptyset) = 0$, $\text{firstTrans}_i(\emptyset) = 0$ and $\text{count}_i(\emptyset) = i$.

Proof: By induction on $i$ since $\emptyset$ is a subset of all transactions in $T$.  

21
Proposition 1 Let $T$ be a transaction sequence relative to some set $I$, $\sigma$ a support sequence and $V_i$ a support lattice relative to $T$ and $\sigma$ up to some positive integer $i$. Let $v$ be a subset of $I$.

1. If $v \in V_i$ then $\text{count}_{\text{firstTrans}_{i-1}}(v) \leq \max\text{Missed}_i(v)$

2. If $\text{support}_i(v) > \text{avg}_i(\lceil \sigma \rceil_i) + \frac{|v|-1}{i}$ then $v \in V_i$.

Proof: Let $T = (t_1, t_2, \ldots)$ be a transaction sequence relative to some set $I$, $\sigma = (\sigma_1, \sigma_2, \ldots)$ a support sequence and $v$ a subset of $I$. We prove Proposition 1 by double induction on $c = |v|$ and on $i$:

Let $c = 0$. Hence $v = \emptyset$. Thus Proposition 1 holds for all $i$ by Lemma 7.

Let $c \geq 1$. Suppose Proposition 1 holds for all subsets of $I$ with less than $c$ elements and all $i$. Let $v \subseteq I$ such that $c = |v|$. We show by induction on $i$ that 1. and 2. hold.

Let $i = 1$.

1. Let $v \in V_1$. By Definition 1 we have $V_1 = \{\emptyset\} \cup \bigcup_{a \in \mathcal{A}} \{a\}$ and $\max\text{Missed}_1(v) = 0 = \text{count}_{T_0}(v)$ for all $v \in V_1$. Hence 1. holds for $i = 1$.

2. Let $\text{support}_1(v) > \text{avg}_1(\lceil \sigma \rceil_1) + \frac{|v|-1}{1}$. Since $c \geq 1$ we have $1 \geq \text{support}_1(v) > \text{avg}_1(\lceil \sigma \rceil_1) + c - 1 \geq 0$.

Hence $c = 1$. Since $\text{support}_1(v) > 0$ we get $v \subseteq t_1$. Hence $v \in V_1 = \{\emptyset\} \cup \bigcup_{a \in \mathcal{A}} \{a\}$.

Let $i > 1$. Suppose 1. and 2. hold for all $i$ if $v \subseteq I$ contains less than $c$ elements and up to $i - 1$ if $v$ contains $c$ elements. We show that 1. and 2. hold for $i$ as well if $v$ contains $c$ elements:

1. Let $v \in V_i$ and $|v| = c$.

   i) Suppose $v \in V_{i-1}$. Thus we get by $\text{firstTrans}_{i-1}(v) = \text{firstTrans}_i(v)$ and the induction hypothesis

   $\text{count}_{\text{firstTrans}_{i-1}}(v) \leq \max\text{Missed}_{i-1}(v) = \max\text{Missed}_i(v)$.

   ii) Suppose $v \notin V_{i-1}$ and there exists a set $w \in \text{subsets}_{i-1}(v)$ such that $\max\text{Missed}_i(v) = \max\text{Missed}_{i-1}(w) + \text{count}_{i-1}(w)$. Since $w \subseteq v$ we have by the induction hypothesis for 1. and Lemma 4

   $\text{count}_{i-1}(w) \leq \text{count}_{i-1}(v) \leq \max\text{Missed}_{i-1}(v) + \text{count}_{i-1}(w)$.

   Since $v \notin V_{i-1}$ but $v \in V_i$ we have $v \subseteq t_i$. By Definition 1 we therefore get

   \[ \text{count}_{i}(v) = \text{count}_{i-1}(v) + 1 \leq \max\text{Missed}_{i-1}(w) + \text{count}_{i-1}(w) + 1 \]

   \[ = \max\text{Missed}_i(v) + 1 \]

   \[ = \max\text{Missed}_i(v) + \text{count}_i(v). \]

Hence 1. follows by Lemma 4 for this case.

iii) Suppose $v \notin V_{i-1}$ and no vertex $w \in \text{subsets}_{i-1}(v)$ exists such that $\max\text{Missed}_i(v) = \max\text{Missed}_{i-1}(w) + \text{count}_{i-1}(w)$. Hence $v \in C_i$,

   $\max\text{Missed}_i(v) = \lceil (i - 1) \cdot \text{avg}_{i-1}(\lceil \sigma \rceil_{i-1}) \rceil + c - 1$. 

22
and \( \text{firstTrans}_i(v) = i \). Suppose \( \text{Count}_i(v) > \maxMissed_i(v) \). Since \( \text{Count}_i(v) \in \mathbb{N} \) we get by the above equality

\[
\text{Support}_i(v) > \text{avg}_i - 1[\sigma]_i + \frac{c-1}{i}.
\]

Thus \( v \in V_{i-1} \) by the induction hypothesis for 2., in contradiction to \( v \notin V_{i-1} \). Hence \( \text{Count}_i(v) \leq \maxMissed_i(v) \).

2. Let \( v \subseteq I \) such that \( |v| = c \) and \( \text{Support}_i(v) > \text{avg}_i([\sigma]_i) + \frac{c-1}{i} \).

i) Suppose \( v \notin t_i \). By Lemma 3 we get

\[
\text{Count}_i(v) = \text{Count}_i(v) = i \cdot \text{Support}_i(v) > i \cdot \text{avg}_i([\sigma]_i) + c - 1
\]

\[
> \sum_{j=1}^{i} [\sigma]_{i,j} + c - 1
\]

\[
\geq \sum_{j=1}^{i-1} [\sigma]_{i-1,j} + c - 1
\]

\[
= (i-1) \cdot \text{avg}_{i-1}([\sigma]_{i-1}) + c - 1.
\]

Hence \( \text{Support}_i(v) > \text{avg}_{i-1}([\sigma]_{i-1}) + \frac{c-1}{i} \). By the induction hypothesis for 2. we get \( v \in V_{i-1} \). By the induction hypothesis for 1. and by \( v \notin t_i \) we get

\[
\maxMissed_i(v) + \text{Count}_i(v) \geq \text{Count}_i(v) > i \cdot \text{avg}_i([\sigma]_i) + c - 1.
\]

Also by \( v \notin t_i \) we have

\[
\maxMissed_i(v) + \text{Count}_i(v) = \maxMissed_{i-1}(v) + \text{Count}_{i-1}(v).
\]

Hence

\[
\maxMissed_i(v) + \text{Count}_i(v) > i \cdot \text{avg}_i([\sigma]_i) + c - 1.
\] (6)

Suppose \( v \in D_i \). Hence \( i \cdot \sigma_i > \maxMissed_i(v) + \text{Count}_i(v) \) and therefore

\[
i \cdot \text{avg}_i([\sigma]_i) > \maxMissed_i(v) + \text{Count}_i(v)
\]

by Lemma 3, in contradiction to inequality (6). Hence \( v \notin D_i \) and therefore \( v \in V_i \).

ii) Suppose \( v \subseteq t_i \) and \( v \in V_{i-1} \). Since \( v \subseteq t_i \) we have \( \text{Count}_i(v) = \text{Count}_{i-1}(v) + 1 \). Since \( v \in V_{i-1} \) we get by the induction hypothesis for 1. and Lemma 4

\[
\maxMissed_i(v) + \text{Count}_i(v) = \maxMissed_{i-1}(v) + \text{Count}_{i-1}(v) + 1
\]

\[
\geq \text{Count}_{i-1}(v) + 1 = \text{Count}_i(v)
\]

\[
> i \cdot \text{avg}_i([\sigma]_i) > i \cdot \sigma_i
\]

Hence \( \text{maxSupport}_i(v) > \sigma_i \). If \( v \in D_i \) then \( \text{maxSupport}_i(v) < \sigma_i \), a contradiction. Thus \( v \notin D_i \) and \( v \in V_i \).

iii) Suppose \( v \subseteq t_i \) and \( v \notin V_{i-1} \). Let \( w \) be a subset of \( v \) of cardinality \( c - 1 \). By \( w \subseteq v \subseteq t_i \) we have

\[
\text{Count}_i(v) + 1 = \text{Count}_i(w) \geq \text{Count}_i(v)
\]

\[
> i \cdot \text{avg}_i([\sigma]_i) + c - 1
\]

23
\[
\begin{align*}
&= \sum_{j=1}^{i} [\sigma]_{i,j} + c - 1 \\
&\geq \sum_{j=1}^{i-1} [\sigma]_{i-1,j} + c - 1 \\
&= (i - 1) \cdot \text{avg}_{i-1}([\sigma]_{i-1}) + c - 1
\end{align*}
\]

Thus \( \text{support}_{i-1}(w) > \text{avg}_{i-1}([\sigma]_{i-1}) + \frac{i - 1}{n} \) and therefore \( w \in V_{i-1} \) by the induction hypothesis for \( i \). By Lemma 6 all subsets \( u \subset v \) are therefore elements of \( V_{i-1} \). By the induction hypothesis for \( i \), we get

\[
\max \text{Missed}_i(u) + \text{count}_i(u) \geq \text{count}_i(T_i(u)) \geq \text{count}_i(T_i(v)) > i \cdot \text{avg}_i([\sigma]_i) \geq i \cdot \sigma_i
\]

for all \( u \subset v \). Hence \( v \) is an element of \( C_i \) and therefore of \( V_i \).

**Theorem 2** Let \( T \) be a transaction sequence of length \( n \), \( \sigma \) a support sequence and \( V \) the subset lattice computed by PhaseI(\( T, \sigma \)). Then for any itemset \( v \)

\[
\text{support}_n(v) > \text{avg}_n([\sigma]_n) + \frac{|v| - 1}{n}
\]

implies \( v \in V \).

Let \( c = \max\{|v| : v \in V, \text{maxSupport}(v) \geq \sigma_n\} \), i.e. the maximal cardinality of all potentially large itemsets in \( V \). Then \( V \) is a support lattice up to \( n \) relative to \( T \) and support threshold

\[
\text{avg}_n([\sigma]_n) + \frac{c+1}{n}
\]

Proof: Let \( T = (t_1, \ldots, t_n) \) be a transaction sequence relative to some set \( I \), \( \sigma = (\sigma_1, \ldots, \sigma_n) \) a support sequence and let \( V_n \) be the lattice defined by Definition 1 with \( D_i \) defined according to the pruning strategy chosen for PhaseI. By Lemma 1 it suffices to proof Theorem 2 for \( V_n \). Let \( v \) be a subset of \( I \). By Proposition 1 we have \( v \in V_n \) if

\[
\text{support}_n(v) > \text{avg}_n([\sigma]_n) + \frac{|v| - 1}{n}.
\]  

(7)

By Lemma 4 and Proposition 1 we get that \( V_n \) is a support lattice up to \( n \) relative to \( T \). Let \( c = \max\{|v| : v \in V, \text{maxSupport}(v) \geq \sigma_n\} \). By Lemma 7 we may assume, without loss of generality, that \( c \geq 1 \). We show that \( V_n \) is a support lattice relative to the support threshold

\[
\text{avg}_n([\sigma]_n) + \frac{c+1}{n}.
\]

Let \( v \) be a subset of \( I \) such that \( \text{support}_n(v) \geq \text{avg}_n([\sigma]_n) + \frac{c+1}{n} \). Suppose \( |v| \geq c+1 \). Thus \( v \) contains a subset \( w \) of cardinality \( c + 1 \). Since \( \text{support}_n(w) \geq \text{support}_n(v) \) inequality (7) holds for \( w \) and thereby \( w \in V_n \), in contradiction to the definition of \( c \). Hence \( |v| \leq c \). Since inequality (7) holds for this case we get \( v \in V_n \). Hence \( V_n \) is a support lattice relative to the support threshold \( \text{avg}_n([\sigma]_n) + \frac{c+1}{n} \).
D PhaseII with Forward Pruning

We extend the PhaseII algorithm described Subsection 6.1 by a “forward pruning” technique. With this technique we can remove during the second scan some small singleton set $v$ and its descendants from $V$ before we reach $firstTrans(v)$, even if $max\text{Support}(v) \geq \sigma_n$. Thereby we reduce the size of the lattice as well as number of transactions which need to be rescanned, speeding up the second phase. The general idea is the following:

Let $v$ be a singleton set in $V$ and suppose $support_n(v) \geq \sigma_n$. Suppose we are rescanning the $i$-th transaction. Thus there are at least $[n \cdot \sigma_n] - count(v)$ occurrences of $v$ in $t_{i+1}, \ldots, t_{ft-1}$ with $ft = firstTrans(v)$. Suppose that $v$ was not contained in $V$ after the $i$-th transaction was processed by PhaseI. At the first occurrence of $v$ after $t_i$, PhaseI inserts $v$ in $V$ with $maxMissed(v) \geq [i \cdot \text{avg}$, $\{\sigma_i\}]$, since $v$ is a singleton. The insertion of $v$ in $V$ is guaranteed to take place, since its only subset is the emptyset which always has support 1. By an induction on $ft - i$ we get that if

$$[n \cdot \sigma] - count(v) + [i \cdot \text{avg}, \{\sigma_i\}] > [(ft - 1)\text{avg}_{ft-1}, \{\sigma_{ft-1}\}]$$

then $v$ had to be in $V$ while the $ft$-th transaction was processed by PhaseI, c.f. Lemma 8. This is in contradiction to the insertion of $v$ in $V$ by PhaseI during the $ft$-th transaction. Hence $support_n(v) < \sigma_n$ and we prune $v$ and all its descendants from $V$ while PhaseII processes the $i$-th transaction. Note that this arguments requires that $v \not\in V$ at the $i$-th transaction in PhaseI and that inequality (8) holds. The following Theorem 3 asserts the correctness of our “forward pruning” technique:

**Theorem 3** Let $T$ be a transaction sequence of length $n$, $\sigma = (\sigma_1, \ldots, \sigma_n)$ a support sequence and $V$ the support lattice returned by PhaseI( $T$, $\sigma$ ). Let $ft = firstTrans_n(v)$ and $i$ some index $< ft$. If $v$ is a singelton set which does not occur in the first $i$ transactions and

$$[n \cdot \sigma_n] - count(v) + [i \cdot \text{avg}, \{\sigma_i\}] > [(ft - 1)\text{avg}_{ft-1}, \{\sigma_{ft-1}\}]$$

then

$$support_n(v) < \sigma_n.$$

Proof: see Theorem 4 in Subsection D.2.

For a straightforward generalization of Theorem 3 to a set $v$ of arbitrary cardinality we need to know: 1) that $v \not\in V$ at the $i$-th transaction of PhaseI and 2) that PhaseI inserts $v$ in the support lattice before transaction $ft$ if the inequality holds. However, for non-singleton sets, this requires knowledge about the PhaseI pruning strategy. For the PhaseI pruning strategy used in Subsection 5.2 this knowledge is available and we might use it to derive a corresponding forward pruning technique for 2-itemsets. Nonetheless this knowledge is in general not available.
D.1 PhaseII Algorithm with Forward Pruning

Adding the forward pruning technique to the PhaseII algorithm described in Subsection 6.1 we get our extended PhaseII algorithm:

Function PhaseII( support lattice \( V \), transaction sequence \((t_1, \ldots, t_n)\), support sequence \( \sigma \) ) : support lattice;

integer \( ft, i = 0 \);
begin
\( V := V \setminus \{ v \in V \mid \text{maxSupport}(v) < \sigma_n \} \);
while \( \exists v \in V : i < \text{firstTrans}(v) \) do
\( i++ \);
for all \( v \in V \) do
\( \text{ft} := \text{firstTrans}(v) ; \)
if \( v \subseteq t_i \) and \( \text{ft} < i \) then \( \text{count}(v)++ \), \( \text{maxMissed}(v)++ \); fi;
if \( \text{ft} = i \) then
\( \text{maxMissed}(v) := 0 \);
for all \( w \in V : v \subseteq w \) and \( \text{maxSupport}(w) > \text{maxSupport}(v) \) do
\( \text{maxMissed}(w) := \text{count}(v) - \text{count}(w) \);
od;
fi;
if \( \text{maxSupport}(v) < \sigma_n \) then \( V := V \setminus \{ v \} \); fi;
if \( |v| = 1 \) and \( v \) does not occur in \( t_1, \ldots, t_i \) and
\[ [n \cdot \sigma_n] - \text{count}(v) + [i \cdot \text{avg}_i([\sigma]_{i, -1})] > [(ft - 1) \text{avg}_{ft-1}([\sigma]_{ft-1})] \]
then
\( V := V \setminus \{ w \in V \mid v \subseteq w \} \);
fi;
od; od;
return \( V \);
end.

Figure 5

D.2 Proof of PhaseII with Forward Pruning

In this subsection we give a proof for the correctness of the PhaseII algorithm with forward pruning. We use the same notation as in Appendix C.

**Lemma 8** Let \( T \) be a transaction sequence, \( \sigma \) a support sequence and \( V_j \) for \( j \geq 1 \) a support lattice relative to \( T \) and \( \sigma \) up to \( j \). Suppose the singleten itemset \( \{a\} \) is not contained in \( V_i \) and

\[
\text{count}_{T_i}(\{a\}) - \text{count}_{T_n}(\{a\}) + \left[ \sum_{k=1}^{i} [\sigma]_{i, k} \right] > \left[ \sum_{k=1}^{n} [\sigma]_{n, k} \right]
\]

(9)
for some positive integers $i$ and $n$ with $i \leq n$. Then 
\[ \{a\} \in V_n. \]

Proof: We prove Lemma 8 by induction on $d = n - i$. Let $T = (t_1, t_2, \ldots)$ and 
$\sigma = (\sigma_1, \sigma_2, \ldots)$. Let $n \geq i$, $a \in I$ such that $\{a\} \not\in V_i$ and suppose that inequality (9) holds. For $d = 0$ the inequality is never satisfied and thus Lemma 8 holds trivially.

Let $d = 1$. Hence $n = i + 1$. Since $\sum_{k=1}^{n} [\sigma]_{n,k} \geq \sum_{k=1}^{i} [\sigma]_{i,k}$ we get by inequality (9) $\text{count}_{T_{i+1}}(\{a\}) = \text{count}_{T_{i}}(\{a\}) \geq 1$.

Thus $a \in t_{i+1}$. By $\{a\} \not\in V_i$ and Definition 1 we get $\{a\} \in V_{i+1} = V_n$. Hence Lemma 8 holds for this case.

Let $d > 1$ and suppose Lemma 8 holds if $n - i < d$.

Suppose $a \not\in t_{i+1}$. Hence $\text{count}_{T_{i+1}}(\{a\}) = \text{count}_{T_{i}}(\{a\})$. Thus Lemma 8 holds for this case by the induction hypothesis.

Suppose $a \in t_{i+1}$. Since $\{a\} \not\in V_i$ we have $\{a\} \in V_{i+1}$ and

\[ \left[ \sum_{k=1}^{i} [\sigma]_{i,k} \right] \leq \text{maxMissed}_{i+1}(\{a\}) \tag{10} \]

by Definition 1. If $\{a\} \in V_j$ for all $j = i + 2, \ldots, n$ then Lemma 8 holds trivially. Suppose that there exists an index $j$ such that $\{a\} \not\in V_j$. We may assume, without loss of generality, that $j$ is minimal. Hence $\{a\} \in D_j$ with $D_j$ defined as in Definition 1. Thus

\[ \text{count}_j(\{a\}) + \text{maxMissed}_j(\{a\}) < j \cdot \sigma_j. \]

Since $j$ is minimal we have $\text{maxMissed}_{i+1}(\{a\}) = \text{maxMissed}_j(\{a\})$. Together with the above inequality and (10) we have

\[ \text{count}_j(\{a\}) + \left[ \sum_{k=1}^{i} [\sigma]_{i,k} \right] < j \cdot \sigma_j. \]

Hence we get by Lemma 3 and Lemma 4

\[ \text{count}_{T_{j}}(\{a\}) = \text{count}_{T_{i}}(\{a\}) + \left[ \sum_{k=1}^{i} [\sigma]_{i,k} \right] < j \cdot \sigma_j \leq \left[ \sum_{k=1}^{i} [\sigma]_{i,k} \right]. \]

By (9) we now have

\[ \text{count}_{T_n}(\{a\}) - \text{count}_{T_i}(\{a\}) + \left[ \sum_{k=1}^{i} [\sigma]_{i,k} \right] \]

\[ - \text{count}_{T_{j}}(\{a\}) + \text{count}_{T_{i}}(\{a\}) - \left[ \sum_{k=1}^{i} [\sigma]_{i,k} \right] \]

\[ > \left[ \sum_{k=1}^{n} [\sigma]_{n,k} \right] - \left[ \sum_{k=1}^{j} [\sigma]_{j,k} \right] \]

yielding $\text{count}_{T_n}(\{a\}) - \text{count}_{T_{j}}(\{a\}) + \left[ \sum_{k=1}^{i} [\sigma]_{i,k} \right] > \left[ \sum_{k=1}^{n} [\sigma]_{n,k} \right]$. Since $j > i$ we get $\{a\} \in V_n$ by the induction hypothesis.
Theorem 4 Let $T$ be a transaction sequence, $\sigma$ a support sequence and $V$ the support lattice returned by PhaseI($T$, $\sigma$). Let $v \in V$ be a singleton set, i.e. $|v| = 1$, $fl = firstTrans_n(v)$ and $countT_i(v) = 0$ for some positive integer $i < fl$. If

$$[n \cdot \sigma_n] - count(v) + [i \cdot \text{avg}_i(\sigma_i)] > [(fl - 1)\text{avg}_{fl-1}(\sigma_{fl-1})]$$

(11)

then

$$support_n(v) < \sigma_n.$$

Proof: Let $\{a\} \in V_n$, $fl = firstTrans_n(\{a\}) > 1$ and $countT_i(\{a\}) = 0$. Suppose (11) holds and $support_n(\{a\}) \geq \sigma_n$. Hence $countT_n(\{a\}) \geq [n \cdot \sigma_n]$ and therefore $countT_{fl-1}(\{a\}) \geq [n \cdot \sigma_n] - count_n(\{a\})$ by Lemma 4. Since $countT_i(\{a\}) = 0$ we get by inequality (11)

$$countT_{fl-1}(\{a\}) - countT_i(\{a\}) + \sum_{k=1}^{i} [\sigma_{i,k}] > \sum_{k=1}^{fl-1} [\sigma_{fl-1,k}].$$

Hence $\{a\}$ is an element of $V_{fl-1}$ by Lemma 8. Since $firstTrans_n(\{a\}) = fl$ we have $\{a\} \in V_{fl-1} \setminus V_{fl-1}$, in contradiction to $\{a\} \in V_{fl-1}$. Thus $support_n(\{a\}) < \sigma_n$.
