June 1994

Abstract

We study the computational complexity of languages which have interactive proofs of logarithmic knowledge complexity. We show that all such languages can be recognized in $\mathcal{BPP}^{\mathcal{NP}}$. Prior to this work, for languages with greater-than-zero knowledge complexity (and specifically, even for knowledge complexity 1) only trivial computational complexity bounds (i.e., only recognizability in $\mathcal{PSPACE} = \mathcal{IP}$) were known. In the course of our proof, we relate statistical knowledge-complexity with perfect knowledge-complexity; specifically, we show that, for the honest verifier, these hierarchies coincide, up to a logarithmic additive term (i.e., $\mathcal{SKC}(k(\cdot)) \subseteq \mathcal{PKC}(k(\cdot) + \log(\cdot))$).

*An extended abstract of this paper is to appear in *The Twenty-sixth ACM Symposium on Theory of Computing* (STOC 94) to be held in Montreal, Quebec, Canada, May 23-25, 1994.

1 Introduction

The notion of knowledge-complexity was introduced in the seminal paper of Goldwasser Micali and Rackoff [GMR-85, GMR-89]. Knowledge-complexity (KC) is intended to measure the *computational advantage* gained by interaction. Satisfactory formulations of knowledge-complexity, for the case that it is not zero, have recently appeared in [GP-91]. A natural suggestion, made by Goldwasser, Micali and Rackoff, is to classify languages according to the knowledge-complexity of their interactive-proofs [GMR-89]. We feel that it is worthwhile to give this suggestion a fair try.

The lowest level of the knowledge-complexity hierarchy is the class of languages having interactive proofs of knowledge-complexity zero, better known as zero-knowledge. Actually, there are three hierarchies extending the three standard definitions of zero-knowledge; namely *perfect*, *statistical* and *computational*. Let us denote the corresponding hierarchies by $\mathcal{PKC}(\cdot)$, $\mathcal{SKC}(\cdot)$, and $\mathcal{CKC}(\cdot)$. Assuming the existence of one-way functions, the third hierarchy collapses, namely $\mathcal{CKC}(0) = \mathcal{CKC}(\text{poly}) = \mathcal{IP}$ [GMW-86, IY-87, B+ 88]. Put differently, the zero level of *computational* knowledge-complexity extends to the maximum possible. Anyhow, in the rest of this paper we will be only interested in the other two hierarchies.

Previous works have provided information only concerning the zero level of these hierarchies. Fortnow has pioneered the attempts to investigate the computational complexity of (perfect/statistical) zero-knowledge [F-89], and was followed by Aiello and Hastad [AH-87]. Their results can be summarized by the following theorem that bounds the computational complexity of languages having zero-knowledge proofs.

Theorem [F-89, AH-87]:

$$\mathcal{SKC}(0) \subseteq \mathcal{AM} \cap \text{co-}\mathcal{AM}$$

Hence, languages having statistical zero-knowledge must lie in the second level of the polynomial-time hierarchy. Needless to say that $\mathcal{PKC}(k(\cdot)) \subseteq \mathcal{SKC}(k(\cdot))$, for any function k and in particular for $k \equiv 0$.

On the other hand, if we allow polynomial amount of knowledge to be revealed, then every language in \mathcal{IP} can be proven.

Theorem [LFKN-90, Sh-90]:

$$\mathcal{PKC}(\text{poly}(\cdot)) = \mathcal{IP} = \mathcal{PSPACE}$$

As indicated in [GP-91], the first equality is a property of an adequate definition (of knowledge complexity) rather than a result.

In this paper we study the class of languages that have interactive-proofs with logarithmic knowledge-complexity. In particular, we bound the computational complexity of languages having interactive proofs of logarithmic knowledge complexity,

showing that they can be recognized by probabilistic polynomial-time machines with access to an NP oracle.

Main Theorem:

$$SKC(O(\log(\cdot))) \subseteq \mathcal{BPP}^{\mathcal{NP}}$$

We recall that $\mathcal{BPP}^{\mathcal{NP}}$ is contained in the third level of the polynomial-time hierarchy (\mathcal{PH}). It is believed that \mathcal{PH} is a proper subset of \mathcal{PSPACE} . Thus, assuming $\mathcal{PH} \subsetneq \mathcal{PSPACE}$, our result yields the first proof that there exist languages in \mathcal{PSPACE} which cannot be proven by an interactive-proof that yields $O(\log n)$ bits of knowledge. In other words, there exist languages which do have interactive proofs but only interactive proofs with super-logarithmic knowledge-complexity.

Prior to our work, there was no solid indication¹ that would contradict the possibility that all languages in \mathcal{PSPACE} have interactive-proofs which yield only *one bit of knowledge*. The only attempt to bound the computational complexity of languages having interactive proofs of low knowledge-complexity was done by Bellare and Petrank. Yet, their work refers only to languages having interactive proofs that are **both** of *few rounds* and of *low knowledge complexity* [BP-92]. Specifically, they showed that if a language L has a $r(n)$ -round interactive-proof of knowledge-complexity $O(\frac{\log n}{r(n)})$ then the language can be recognized in $\mathcal{BPP}^{\mathcal{NP}}$.

Our proof of the Main Theorem consists of two parts. In the first part, we show that the procedure described by Bellare and Petrank [BP-92] suffices for recognizing languages having interactive proofs of logarithmic *perfect* knowledge complexity. To this end, we use a more careful analysis than the one used in [BP-92]. In the second part of our proof we transform interactive proofs of *statistical* knowledge complexity $k(n)$ into interactive proofs of *perfect* knowledge complexity $k(n) + \log n$. This transformation refers only to knowledge-complexity with respect to the honest verifier, but this suffices since the first part of our proof applies to the knowledge-complexity with respect to the honest verifier. Yet, the transformation is interesting for its own sake, and a few words are in place.

The question of whether statistical zero-knowledge equals perfect zero-knowledge is one of the better known open problems in this area. The question has been open also for the case of zero-knowledge with respect to the honest verifier. We show that for every poly-time computable function $k: \mathbb{N} \mapsto \mathbb{N}$ (and in particular for $k \equiv 0$)

$$SKC(k(\cdot)) \subseteq \mathcal{PKC}(k(\cdot) + \log(\cdot))$$

This result may be considered an indication that these two hierarchies may collide.

¹Alas, if one had been willing to assume that all languages in \mathcal{PSPACE} have interactive proofs of *logarithmically many rounds*, an assumption that we consider unreasonable, then the result in [BP-92] would have yielded a proof that \mathcal{PSPACE} is not contained in $SKC(1)$, provided (again) that $\mathcal{PH} \subsetneq \mathcal{PSPACE}$.

Techniques Used

As stated above, the first part of our proof consists of presenting a more careful analysis of an existing procedure, namely the procedure suggested by Bellare and Petrank in [BP-92]. Their procedure, in turn, is a culmination of two sequences of works discussed below.

The first sequence originates in Fortnow’s definition of a simulator-based prover [F-89]. Fortnow [F-89], and consequently Aiello and Hastad [AH-87], used the simulator-based prover in order to infer, by way of contradiction, bounds on the sizes of specific sets. A more explicit usage of the simulator-based prover was introduced by Bellare, Micali and Ostrovsky [BMO-90]; specifically, they have suggested to use a PSPACE-implementation of the simulator-based prover, instead of using the original prover (of unbounded complexity) witnessing the existence of a zero-knowledge interactive proof system. (Thus, they obtained a bound on the complexity of provers required for zero-knowledge proof systems.) Ostrovsky [Ost-91] suggested to use an implementation of the interaction between the verifier and the simulation-based prover as a procedure for deciding the language. Furthermore, assuming that one-way functions do not exist, he used “universal extrapolation” procedures of [ILu-90, ILe-90] to approximate the behavior of the simulator-based prover. (Thus, assuming that one-way function do not exist, he presented an efficient procedure that decides languages in $\mathcal{SKC}(0)$ and inferred that one-way functions are essential to the non-triviality of statistical zero-knowledge). Bellare and Petrank distilled the decision procedure from the context of one-way functions, showing that the simulator-based prover can be implemented using a perfect universal extrapolator (also known as a “uniform generation” procedure) [BP-92]. The error in the implementation is directly related to the deviation of the uniform generation procedure.

The second sequence of works deals with the two related problems of approximating the size of sets and uniformly generating elements in them. These problems were related by Jerrum et. al. [JVV-86]. Procedures for approximating the size of sets were invented by Sipser [Si-83] and Stockmeyer [St-83], and further improved in [GS-89, AH-87], all using the “hashing paradigm”. The same hashing technique, is the basis of the “universal extrapolation” procedures of [ILu-90, ILe-90]. However, the output of these procedures deviates from the objective (i.e., uniform distribution on the target set) by a non-negligible amount (i.e., $1/\text{poly}(T)$ when running for time T). On the other hand, Jerrum et. al. have also pointed out that (perfect) uniform generation can be done by a $\mathcal{BPP}^{\Sigma_2^P}$ -procedure [JVV-86]. Bellare and Petrank combined the hashing-based approximation methods with the ideas of [JVV-86] to obtain a $\mathcal{BPP}^{\mathcal{NP}}$ -procedure for uniform generation with exponentially vanishing error probability [BP-92]. Actually, if the procedure is allowed to halt with no output with constant (or exponentially vanishing) probability, then its output distribution is exactly uniform on the target set.

Motivation for studying KC

In addition to the self-evident fundamental appeal of knowledge complexity, we wish to point out some practical motivation for considering knowledge-complexity greater than zero. In particular, cryptographic protocols that release a small (i.e., logarithmic) amount of knowledge may be of practical value, especially if they are only applied once or if one can obtain sub-additive bounds on the knowledge complexity of their repeated executions. Note that typically, a (single application of a) sub-protocol leaking logarithmically many bits (of knowledge) does not compromise the security of the entire protocol. The reason being that these (logarithmically many) bits can be guessed with non-negligible probability, which in turn means that any attack due to the “leaked bits” can be simulated with non-negligible probability without them.

But why use low knowledge-complexity protocols when one can use zero-knowledge ones (see, [GMW-86, GMW-87])? The reason is that the non-zero-knowledge protocols may be more efficient and/or may require weaker computational assumptions (see, for example, [OVY-91]).

Remarks

A remark concerning two definitions. Throughout the paper, $\mathcal{SKC}(k(\cdot))$ and $\mathcal{PKC}(k(\cdot))$ denote the classes of knowledge-complexity *with respect to the honest verifier*. Note that the Main Theorem is only strengthened by this, whereas the transformation (mentioned above) is indeed weaker. Furthermore, by an interactive proof we mean one in which the *error probability is negligible* (i.e., smaller than any polynomial fraction). A few words of justification appear in Section 2.

A remark concerning Fortnow’s paper [F-89]. In course of this research, we found out that the proof that $\mathcal{SKC}(0) \subseteq \text{co-}\mathcal{AM}$ as it appears in [F-89] is not correct. In particular, there is a flaw in the AM-protocol presented in [F-89] for the complement language (see Appendix). However, the paper of Aiello and Hastad provides all the necessary machinery for proving Fortnow’s result as well [AH-87, H-94]. Needless to say that the basic approach presented by Fortnow (i.e., looking at the “simulator-based prover”) is valid and has inspired all subsequent works (e.g., [AH-87, BMO-90, Ost-91, BP-92, OW-93]) as well as the current one.

2 Preliminaries

Let us state some of the definitions and conventions we use in the paper. Throughout this paper we use n to denote the length of x .

2.1 Interactive proofs

Let us recall the concept of interactive proofs, presented by [GMR-89]. For formal definitions and motivating discussions the reader is referred to [GMR-89]. A protocol

between a (computationally unbounded) *prover* P and a (probabilistic polynomial-time) *verifier* V constitutes an **interactive proof** for a language L if there exists a negligible function $\epsilon : \mathbb{N} \rightarrow [0, 1]$ (i.e., for every polynomial p and all sufficiently large n 's $\epsilon(n) < \frac{1}{p(n)}$) such that

1. **Completeness**: If $x \in L$ then

$$\Pr[(P, V)(x) \text{ accepts}] \geq 1 - \epsilon(n)$$

2. **Soundness**: If $x \notin L$ then for any prover P^*

$$\Pr[(P^*, V)(x) \text{ accepts}] \leq \epsilon(n)$$

Remark: Usually, the definition of interactive proofs is robust to setting the error probability to be bounded away from $\frac{1}{2}$, since the error probability can be reduced by repetitions. However, this standard procedure is not applicable when knowledge-complexity is measured, since (even sequential) repetitions may increase the knowledge-complexity. The question is, thus, what is the *right* definition. The definition used above is quite standard and natural; it is certainly less arbitrary than setting the error to be some favorite constant (e.g., $\frac{1}{3}$) or function (e.g., 2^{-n}). Yet, our techniques yield non-trivial results also in case one defines interactive proofs with non-negligible error probability (e.g., constant error probability). Details are omitted. Also note that we have allowed two-sided error probability; this strengthens our main result but weakens the statistical to perfect transformation².

2.2 Knowledge Complexity

Throughout the rest of the paper, we refer to knowledge-complexity *with respect to the honest verifier*; namely, the ability to simulate the (honest) verifier's view of its interaction with the prover. (In the stronger definition, one considers the ability to simulate the point of view of *any efficient verifier* while interacting with the prover.)

We let $(P, V)(x)$ denote the random variable that represents V 's view of the interaction with P on common input x . The view contains the verifier's random tape as well as the sequence of messages exchanged between the parties.

We begin by briefly recalling the definitions of perfect and statistical zero-knowledge. A protocol (P, V) is *perfect zero-knowledge* (resp., *statistical zero-knowledge*) if there is a probabilistic polynomial time simulator M such that the random variable $M(x)$ is distributed identically to $(P, V)(x)$ (resp., the statistical difference between $M(x)$ and $(P, V)(x)$ is a negligible function in $|x|$).

²Suppose you had a transformation for the one-sided case. Then, given a two-sided interactive proof of some statistical knowledge complexity you could have transformed it to a one-sided error proof of the same knowledge complexity (cf., [GMS-87]). Applying the transformation for the one-sided case would have yielded an even better result.

Next, we present the definitions of perfect (resp., statistical) knowledge-complexity which we use in the sequel. These definitions extend the definition of perfect (resp., statistical) zero-knowledge, in the sense that knowledge-complexity zero is exactly zero-knowledge. Actually, there are two alternative formulations of knowledge-complexity, called the *oracle version* and the *fraction version*. These formulations coincide at the zero level and differ by at most an additive constant otherwise [GP-91]. For further intuition and motivation see [GP-91]. It will be convenient to use both definitions in this paper³.

By the *oracle formulation*, the knowledge-complexity of a protocol (P, V) is the number of oracle (bit) queries that are needed to simulate the protocol efficiently.

Definition 2.1 (knowledge complexity — oracle version): *Let $k: \mathbf{N} \rightarrow \mathbf{N}$. We say that an interactive proof (P, V) for a language L has perfect (resp., statistical) knowledge complexity $k(n)$ in the oracle sense if there exists a probabilistic polynomial time oracle machine M and an oracle A such that:*

1. *On input $x \in L$, machine M queries the oracle A for at most $k(|x|)$ bits.*
2. *For each $x \in L$, machine M^A produces an output with probability at least $\frac{1}{2}$, and given that M^A halts with an output, $M^A(x)$ is identically distributed (resp., statistically close) to $(P, V)(x)$.*

In the *fraction formulation*, the simulator is not given any explicit help. Instead, one measures the density of the largest subspace of simulator’s executions (i.e., coins) which is identical (resp., close) to the (P, V) distribution.

Definition 2.2 (knowledge complexity — fraction version): *Let $\rho: \mathbf{N} \rightarrow (0, 1]$. We say that an interactive proof (P, V) for a language L has perfect (resp., statistical) knowledge-complexity $\log_2(1/\rho(n))$ in the fraction sense if there exists a probabilistic polynomial-time machine M with the following “good subspace” property. For any $x \in L$ there is a subset of M ’s possible random tapes S_x , such that:*

1. *The set S_x contains at least a $\rho(|x|)$ fraction of the set of all possible coin tosses of $M(x)$.*
2. *Conditioned on the event that $M(x)$ ’s coins fall in S_x , the random variable $M(x)$ is identically distributed (resp., statistically close) to $(P, V)(x)$. Namely, for the perfect case this means that for every \bar{c}*

$$\text{Prob}(M(x, \omega) = \bar{c} \mid \omega \in S_x) = \text{Prob}((P, V)(x) = \bar{c})$$

where $M(x, \omega)$ denotes the output of the simulator M on input x and coin tosses sequence ω .

³The analysis of the [BP-92] procedure is easier when using the fraction version, whereas the transformation from statistical to perfect is easier when using the oracle version.

It is shown in [GP-91] that these two measures are almost equal.

Theorem [GP-91]: The fraction measure and the oracle measure are equal up to an additive constant.

Since none of our results is sensitive to a difference of an additive constant in the measure, we ignore this difference in the subsequent definition as well as in the statement of our results.

Definition 2.3 (knowledge complexity classes):

- $\mathcal{PKC}(k(\cdot)) =$ languages having interactive proofs of perfect knowledge complexity $k(\cdot)$.
- $\mathcal{SKC}(k(\cdot)) =$ languages having interactive proofs of statistical knowledge complexity $k(\cdot)$.

2.3 The simulation based prover

An important ingredient in our proof is the notion of a simulation based prover, introduced by Fortnow [F-89]. Consider a simulator M that outputs conversations of an interaction between a prover P and a verifier V . We define a new prover P^* , called *the simulation based prover*, which selects its messages according to the conditional probabilities induced by the simulation. Namely, on a partial history h of a conversation, P^* outputs a message α with probability

$$\text{Prob}(P^*(h) = \alpha) \stackrel{\text{def}}{=} \text{Prob}(M_{|h|+1} = h \circ \alpha \mid M_{|h|} = h)$$

where M_t denotes the distribution induced by M on t -long prefixes of conversations. (Here, the length of a prefix means the number of messages in it.)

It is important to note that the behavior of P^* is not necessarily close to the behavior of the original prover P . Specifically, if the knowledge complexity is greater than 0 and we consider the simulator guaranteed by the fraction definition, then P^* and P might have quite a different behavior. Our main objective will be to show that in this case P^* still behaves in a manner from which we can benefit.

3 The Perfect Case

In this section we prove that the Main Theorem holds for the special case of *perfect* knowledge complexity. Combining this result with the transformation (Theorem 2) of the subsequent section, we get the Main Theorem.

Theorem 1 $\mathcal{PKC}(O(\log n)) \subseteq \mathcal{BPP}^{\mathcal{NP}}$

Our proof follows the procedure suggested in [BP-92], which in turn follows the approach of [F-89, BMO-90, Ost-91] while introducing a new uniform generation procedure which builds on ideas of [Si-83, St-83, GS-89, JVV-86] (see introduction).

Suppose that (P, V) is an interactive proof of perfect knowledge complexity $k(\cdot) = O(\log n)$ for the languages L , and let M be the simulator guaranteed by the fraction formulation (i.e., Definition 2.2). We consider the conversations of the original verifier V with the simulation-based-prover P^* (see definition in §2.3). We are going to show that the probability that the interaction (P^*, V) is accepting is negligible if $x \notin L$ and greater than a polynomial fraction if $x \in L$. Our proof differs from [BP-92] in the analysis of the case $x \in L$ (and thus we get a stronger result although we use the same procedure). This separation between the cases $x \notin L$ and $x \in L$ can be amplified by sequential repetitions of the protocol (P^*, V) . So it remains to observe that we can sample the (P^*, V) interactions in probabilistic polynomial-time having access to an NP oracle. This observation originates from [BP-92] and is justified as follows. Clearly, V 's part of the interaction can be produced in polynomial-time. Also, by the uniform generation procedure of [BP-92] we can implement P^* by a probabilistic polynomial time machine that has access to an NP oracle. Actually, the implementation may fail with negligible probability, but this does not matter. Thus, it remains only to prove the following lemma.

Lemma 3.1

1. If $x \in L$ then the probability that (P^*, V) outputs an accepting conversation is at least $\frac{1}{2} \cdot 2^{-k}$.
2. If $x \notin L$ then the probability that (P^*, V) outputs an accepting conversation is negligible.

Remark: In [BP-92], a weaker lemma is proven. Specifically, they show that the probability that (P^*, V) output an accepting conversation (on $x \in L$) is related to $2^{-k \cdot t}$, where t is the number of rounds in the protocol. Note that in our proof t could be an arbitrary polynomial number of rounds.

proof: The second part of the lemma follows from the soundness property as before. We thus concentrate on the first part. We fix an arbitrary $x \in L$ for the rest of the proof and allow ourselves not to mention it in the sequel discussion and notation. Let $k = k(|x|)$ and q be the number of coin tosses made by M . We denote by $\Omega \stackrel{\text{def}}{=} \{0, 1\}^q$ the set of all possible coin tosses, and by S the “good subspace” of M (i.e., S has density 2^{-k} in Ω and for ω chosen uniformly in S the simulator outputs exactly the distribution of the interaction (P, V)).

Consider the conversations that are output by the simulator on $\omega \in S$. The probability to get such a conversation when the simulator is run on ω uniformly selected in Ω , is at least 2^{-k} . We claim that the probability to get these conversations in the interaction (P^*, V) is also at least 2^{-k} . This is not obvious, since the distribution

produced by (P^*, V) may not be identical to the distribution produced by M on a uniformly selected $\omega \in \Omega$. Nor is it necessarily identical to the distribution produced by M on a uniformly selected $\omega \in S$. However, the prover's moves in (P^*, V) are distributed as in the case that the simulator selects ω uniformly in Ω , whereas the verifier's moves (in (P^*, V)) are distributed as in the case that the simulator selects ω uniformly in S . Thus, it should not be too surprising that the above claim can be proven.

However, we need more than the above claim: It is not enough that the (P^*, V) conversations have an origin in S , they must be *accepting* as well. (Note that this is not obvious since M simulates an interactive proof that may have two-sided error.) Again, the density of the accepting conversations in the “good subspace” of M is high (i.e., $\geq 1 - \epsilon$), yet we need to show that this is the case also for the (P^*, V) interaction. Actually, we will show that the probability than an (P^*, V) conversation is accepting and “has an origin” in S is at least $\frac{1}{2} \cdot 2^{-k}$.

Let us begin the formal argument with some notations. For each possible history of the interaction, h , we define subsets of the random tapes of the simulator (i.e., subsets of Ω) as follows. Ω_h is the set of $\omega \in \Omega$ which cause the simulator to output a conversation with prefix h . S_h is the subset of ω 's in Ω_h which are also in S . A_h is the set of ω 's in S_h which are also accepting.

Thus, letting $M_t(\omega)$ denote the t -message long prefix output by the simulator M on coins ω , we get

$$\begin{aligned} \Omega_h &\stackrel{\text{def}}{=} \{\omega : M_{|h|}(\omega) = h\} \\ S_h &\stackrel{\text{def}}{=} \Omega_h \cap S \\ A_h &\stackrel{\text{def}}{=} \{\omega \in S_h : M(\omega) \text{ is accepting}\} \end{aligned}$$

Let C be a random variable representing the (P^*, V) interaction, and χ be an indicator so that $\chi(\bar{c}) = 1$ if the conversation \bar{c} is accepting and $\chi(\bar{c}) = 0$ otherwise. Our aim is to prove that $\text{Prob}(\chi(C) = 1) \geq \frac{1}{2} \cdot 2^{-k}$. Note that

$$\begin{aligned} \text{Prob}(\chi(C) = 1) &= \sum_{\bar{c}} \text{Prob}(C = \bar{c}) \cdot \chi(\bar{c}) \\ &\geq \sum_{\bar{c}} \text{Prob}(C = \bar{c}) \cdot \frac{|A_{\bar{c}}|}{|\Omega_{\bar{c}}|} \end{aligned}$$

The above expression is exactly the expectation value of $\frac{|A_c|}{|\Omega_c|}$. Thus, we need to show that:

$$\text{Exp}_{\bar{c}} \left(\frac{|A_{\bar{c}}|}{|\Omega_{\bar{c}}|} \right) > \frac{1}{2} \cdot 2^{-k} \tag{1}$$

where the expectation is over the possible conversations \bar{c} as produced by the interaction (P^*, V) . Once Equation (1) is proven, we are done. Denote the empty history

by λ . To prove Equation (1) it suffices to prove that

$$\text{Exp}_{\bar{c}} \left(\frac{|A_{\bar{c}}|}{|\Omega_{\bar{c}}|} \cdot \frac{|A_{\bar{c}}|}{|S_{\bar{c}}|} \right) \geq \frac{|A_{\lambda}|}{|\Omega_{\lambda}|} \cdot \frac{|A_{\lambda}|}{|S_{\lambda}|} \quad (2)$$

(since $\frac{|A_{\lambda}|}{|S_{\lambda}|} > \sqrt{\frac{1}{2}}$ and $\frac{|S_{\lambda}|}{|\Omega_{\lambda}|} \geq 2^{-k}$). The proof is by induction on the number of rounds. Namely, for each round i , we show that the expected value of $\frac{|A_h|}{|\Omega_h|} \cdot \frac{|A_h|}{|S_h|}$ over all possible histories h of length i rounds is greater or equal to the expected value of this expression over all histories h of $i - 1$ rounds. In order to show the induction step we consider two cases:

1. the current step is by the prover (i.e., P^*); and
2. the current step is by the verifier (i.e., V).

In both cases we show, for any history h and any possible next message m ,

$$\text{Exp}_m \left(\frac{|A_{hom}|}{|\Omega_{hom}|} \cdot \frac{|A_{hom}|}{|S_{hom}|} \right) \geq \frac{|A_h|}{|\Omega_h|} \cdot \frac{|A_h|}{|S_h|} \quad (3)$$

where the expectation is over the possible current moves m , given history h , as produced by the interaction (P^*, V) .

Technical Claim

The following technical claim, proven in Appendix A, is used for deriving the inequalities in both cases. The claim is that for non-negative $x_i, y_i, 1 \leq i \leq n$

$$\sum_i \frac{x_i^2}{y_i} \geq \frac{(\sum_{i=1}^n x_i)^2}{\sum_{i=1}^n y_i}$$

Prover Step – denoted α

Given history h , the prover P^* sends α as its next message with probability $\frac{|\Omega_{h\alpha}|}{|\Omega_h|}$. Thus,

$$\begin{aligned} \text{Exp}_{\alpha} \left(\frac{|A_{h\alpha}|}{|\Omega_{h\alpha}|} \cdot \frac{|A_{h\alpha}|}{|S_{h\alpha}|} \right) &= \sum_{\alpha} \frac{|\Omega_{h\alpha}|}{|\Omega_h|} \cdot \frac{|A_{h\alpha}|}{|\Omega_{h\alpha}|} \cdot \frac{|A_{h\alpha}|}{|S_{h\alpha}|} \\ &= \frac{1}{|\Omega_h|} \cdot \sum_{\alpha} \frac{|A_{h\alpha}|^2}{|S_{h\alpha}|} \\ &\geq \frac{|A_h|}{|\Omega_h|} \cdot \frac{|A_h|}{|S_h|} \end{aligned}$$

The inequality is justified by using the Technical Claim and noting that $\sum_{\alpha} |A_{h\alpha}| = |A_h|$ and $\sum_{\alpha} |S_{h\alpha}| = |S_h|$.

Verifier Step – denoted β

By the perfectness of the simulation, when restricted to the good subspace S , we know that given history h , the verifier V sends β as its next message with probability $\frac{|S_{h\circ\beta}|}{|S_h|}$. Thus,

$$\begin{aligned} \text{Exp}_\beta \left(\frac{|A_{h\circ\beta}|}{|\Omega_{h\circ\beta}|} \cdot \frac{|A_{h\circ\beta}|}{|S_{h\circ\beta}|} \right) &= \sum_\beta \frac{|S_{h\circ\beta}|}{|S_h|} \cdot \frac{|A_{h\circ\beta}|}{|\Omega_{h\circ\beta}|} \cdot \frac{|A_{h\circ\beta}|}{|S_{h\circ\beta}|} \\ &= \frac{1}{|S_h|} \cdot \sum_\beta \frac{|A_{h\circ\beta}|^2}{|\Omega_{h\circ\beta}|} \\ &\geq \frac{|A_h|}{|\Omega_h|} \cdot \frac{|A_h|}{|S_h|} \end{aligned}$$

The inequality is justified by using the Technical Claim and noting that $\sum_\beta |A_{h\circ\beta}| = |A_h|$ and $\sum_\beta |\Omega_{h\circ\beta}| = |\Omega_h|$.

Having proven Equation (3) for both cases, Equation (2) follows and so does the lemma. \square

4 The Transformation

In this section we show how to transform *statistical* knowledge complexity into *perfect* knowledge complexity, incurring only a logarithmic additive term. This transformation combined with Theorem 1 yields the Main Theorem.

Theorem 2 *For every (poly-time computable) $k : \mathbb{N} \mapsto \mathbb{N}$,*

$$SKC(k(\cdot)) \subseteq PKC(k(\cdot) + O(\log(\cdot)))$$

We stress again that these knowledge complexity classes refer to the honest verifier and that we don't know whether such a result holds for the analogous knowledge complexity classes referring to arbitrary (poly-time) verifiers.

proof: Here we use the oracle formulation of knowledge complexity (see Definition 2.1). We start with an overview of the proof. Suppose we are given a simulator M which produces output that is *statistically close* to the real prover-verifier interaction. We change both the interactive proof and its simulation so that they produce exactly the same distribution space. We will take advantage of the fact that the prover in the interactive proof and the oracle that “assists” the simulator are both infinitely powerful. Thus, the modification to the prover's program and the augmentation to the oracle need not be efficiently computable. We stress that the modification to the simulator itself will be efficiently computable. Also, we maintain the original verifier (of the interactive proof), and thus the resulting interactive proof is still sound.

Furthermore, the resulting interaction will be statistically close to the original one (on any $x \in L$) and therefore the completeness property of the original interactive proof is maintained (although the error probability here may increase by a negligible amount).

Preliminaries

Let $L \in \mathcal{SKC}(k(\cdot))$, and (P, V) be the guaranteed interactive proof. Without loss of generality, we may assume that all messages are of length 1. The message-length convention is merely a matter of encoding.

Recall that Definition 2.1 only guarantees that the simulator produces output with probability $\geq \frac{1}{2}$. Yet, employing Proposition 3.8 in [GP-91], we get that there exists an oracle machine M , that after asking $k(n) + 2 \log \log n$ queries, *always* produces an output so that the output is statistically close to the interaction of (P, V) . Let A denote the associated oracle, and let $M' \stackrel{\text{def}}{=} M^A$ and P' and V' be the simulation-based prover and verifier⁴ induced by M' (i.e., $(P', V') = M'$).

notations: Let $[A, B]_i$ be a random variable representing the i -message (i -bit) long prefix of the interaction between A and B (the common input is implicit in the notation). We denote by $A(h)$ the random variable representing the message sent by A after interaction-history h . Thus, if the i^{th} message is sent by A , we can write $[A, B]_{i-1} \circ A([A, B]_{i-1}) = [A, B]_i$. By $X \stackrel{s}{=} Y$ we denote the fact that the random variables X and Y are statistically close.

Claim 4.1 *The distribution induced by (P', V) is statistically close to the distributions induced by both $M' = (P', V')$ and (P, V) .*

proof: By definition, the distributions produced by $M' = (P', V')$ and (P, V) are statistically close. Thus, we have

$$[P, V]_i \stackrel{s}{=} [P', V']_i, \quad \text{for every } i \tag{4}$$

We prove that $[P', V]$ is statistically close to $[P', V']$ by induction on the length of the interaction. Assuming that $[P', V]_i \stackrel{s}{=} [P', V']_i$, we wish to prove it for $i + 1$. We distinguish two cases. In case the $i + 1^{\text{st}}$ move is by the prover, we get

$$\begin{aligned} [P', V]_{i+1} &= [P', V]_i \circ P'([P', V]_i) \\ &\stackrel{s}{=} [P', V']_i \circ P'([P', V']_i) \\ &= [P', V']_{i+1} \end{aligned}$$

⁴A simulator-based verifier is defined analogously to the simulator-based prover. It is a fictitious entity which does not necessarily coincide with V .

(use the induction hypothesis for $\stackrel{s}{=}$). In case the $i + 1^{\text{st}}$ move is by the verifier, we get

$$\begin{aligned}
[P', V]_{i+1} &= [P', V]_i \circ V([P', V]_i) \\
&\stackrel{s}{=} [P', V']_i \circ V([P', V']_i) \\
&\stackrel{s}{=} [P, V]_i \circ V([P, V]_i) \\
&= [P, V]_{i+1} \\
&\stackrel{s}{=} [P', V']_{i+1}
\end{aligned}$$

where the first $\stackrel{s}{=}$ is justified by the induction hypothesis and the two others by Eq. (4). We stress that since the induction hypothesis is used only once in the induction step, the statistical distance is linear in the number of induction steps (rather than exponential). \square

Motivating discussion: Note that the statistical difference between the interaction (P', V) and the simulation $M' = (P', V')$ is due solely to the difference between the proper verifier (i.e., V) and the verifier induced by the simulator (i.e., V'). This difference may be due to V' putting too much probability weight on certain moves or putting too little weight. The first case is relatively easy to deal with since one can always decrease the probability that the simulator outputs certain conversations (by properly augmenting the oracle). The second case is more problematic and it is required to modify the prover P' so that it gives up its attempt to convince the verifier in these cases (the simulator will be modified as well). Details follow.

Technical remark: The oracle can be used to allow the simulator to toss bias coins when the simulator does not “know” the bias. Suppose that the simulator needs to toss a coin so that it comes-up **head** with probability $\frac{N}{2^m}$, where $N < 2^m$ and both N and m are integers. The simulator supplies the oracle with a uniformly chosen $r \in \{0, 1\}^m$ and the oracle answers **head** if r is among the first N strings in $\{0, 1\}^m$ and **tail** otherwise. A similar procedure is applicable for implementing a lottery with more than two a-priori known values. Using this procedure, we can get extremely good approximations of probability spaces at a cost related to the a-priori known size of the support (i.e., the oracle answer is logarithmic in the size of the support).

Definition: Let $\epsilon \stackrel{\text{def}}{=} \frac{1}{O(t)}$ where t is the number of rounds in the interaction (P, V) .

- Let h be a partial history of the interaction and β be a possible next move by the verifier. We say that β is *weak* with respect to h if

$$\text{Prob}(V'(h) = \beta) < (1 - \epsilon) \cdot \text{Prob}(V(h) = \beta)$$

- A conversation $\bar{c} = (c_1, \dots, c_t)$ is *i-weak* if c_i is weak with respect to (c_1, \dots, c_{i-1}) , otherwise it is *i-good*. (Note that a conversation can be *i-weak* only if the i^{th} move is a verifier move.)

- A conversation $\bar{c} = (c_1, \dots, c_t)$ is *i-critical* if it is *i-weak* but *j-good* for every $j < i$.
A conversation $\bar{c} = (c_1, \dots, c_t)$ is *i-co-critical* if the conversation obtained from \bar{c} , by complementing (only) the i^{th} bit, is *i-critical*. (Note that a conversation can be *i-critical* only for a single i , yet it may be *i-co-critical* for many i 's.)
- A conversation is *weak* if it is *i-weak* for some i , otherwise it is *good*.

Claim 4.2 (P', V) outputs weak conversations with negligible probability.

proof: Recall that $[P', V] \stackrel{\text{s}}{=} [P', V']$ and that the same holds also for prefixes of the conversations. Namely, for any $1 \leq i \leq t$, $[P', V]_i \stackrel{\text{s}}{=} [P', V']_i$. Let us define a prefix $h \in \{0, 1\}^i$ of a conversation to be *bad* if either

$$\text{Prob}([P', V']_i = h) < \left(1 - \frac{\epsilon}{2}\right) \cdot \text{Prob}([P', V]_i = h)$$

or

$$\text{Prob}([P', V']_i = h) > \left(1 + \frac{\epsilon}{2}\right) \cdot \text{Prob}([P', V]_i = h)$$

The claim follows by combining two facts.

Fact 4.3 The probability that (P', V) outputs a conversation with a bad prefix is negligible.

proof: Define B_i to be the set of bad prefixes of length i . By the statistical closeness of $[P', V]_i$ and $[P', V']_i$, we get that

$$\Delta \stackrel{\text{def}}{=} \sum_{h \in B_i} |\text{Prob}([P', V]_i = h) - \text{Prob}([P', V']_i = h)| \leq \gamma$$

for some negligible fraction γ . On the other hand, Δ can be bounded from below by

$$\sum_{h \in B_i} \text{Prob}([P', V]_i = h) \cdot \left| 1 - \frac{\text{Prob}([P', V']_i = h)}{\text{Prob}([P', V]_i = h)} \right|$$

which by definition of B_i is at least

$$\text{Prob}([P', V]_i \in B_i) \cdot \left| \pm \frac{\epsilon}{2} \right|$$

Thus, $\text{Prob}([P', V]_i \in B_i) \leq \frac{2\gamma}{\epsilon}$ and the fact follows. \square

Fact 4.4 If a conversation $\bar{c} = (c_1, \dots, c_t)$ is weak then it contains a bad prefix.

proof: Suppose that $\beta \stackrel{\text{def}}{=} c_{i+1}$ is weak with respect $h \stackrel{\text{def}}{=} (c_1, \dots, c_i)$. If h is a bad prefix then we are done. Otherwise it holds that

$$\text{Prob}([P', V']_i = h) < \left(1 + \frac{\epsilon}{2}\right) \cdot \text{Prob}([P', V]_i = h)$$

Using the fact that β is weak with respect to h , we get

$$\begin{aligned} \text{Prob}([P', V']_{i+1} = h \circ \beta) &< \left(1 + \frac{\epsilon}{2}\right) \cdot (1 - \epsilon) \cdot \text{Prob}([P', V]_{i+1} = h \circ \beta) \\ &< \left(1 - \frac{\epsilon}{2}\right) \cdot \text{Prob}([P', V]_{i+1} = h \circ \beta) \end{aligned}$$

which implies that $h \circ \beta$ is a bad prefix of \bar{c} . \square

Joining Facts 4.3 and 4.4, the proof of Claim 4.2 follows. \square

Claim 4.5 *Suppose that $\bar{c} = (c_1, \dots, c_t)$ is a good conversation. Then, the probability that \bar{c} is output by M' is at least $(1 - \epsilon)^{\lceil t/2 \rceil} \cdot \text{Prob}([P', V] = \bar{c})$. Furthermore, for $l < k$, if $\bar{c} = (c_1, \dots, c_t)$ is i -good for every $i \in \{l + 1, \dots, k\}$, then $\text{Prob}([M']_k = \gamma \mid [M']_l = h)$ is bounded below by*

$$(1 - \epsilon)^{\lceil \frac{k-l}{2} \rceil} \cdot \text{Prob}([P', V]_k = \gamma \mid [P', V]_l = h)$$

where $\gamma \stackrel{\text{def}}{=} (c_1, \dots, c_k)$ and $h \stackrel{\text{def}}{=} (c_1, \dots, c_l)$

proof: To see that this is the case, we write the probabilities step by step conditioned on the history so far. We note that the prover's steps happen with equal probabilities in both sides of the inequality, and therefore can be reduced. Since the relevant verifier's steps are not weak, we get the mentioned inequality. \square

Dealing with weak conversations

We start by modifying the prover P' , resulting in a modified prover, denoted P'' , that stops once it gets a verifier message which is weak with respect to the current history; otherwise, P'' behaves as P' . Next, we modify the simulator so that it outputs either good conversations or truncated conversations which are originally i -critical. The modified simulator, denoted M'' , proceeds as follows⁵. First, it invokes M' and obtains a conversation $\bar{c} = (c_1, \dots, c_t)$. Next, it queries the augmented oracle on \bar{c} . The oracle answers probabilistically and its answers are of the form (i, σ) , where $i \in \{1, \dots, t\}$ and $\sigma \in \{0, 1\}$. The probability distribution will be specified below, at this point we only wish to remark that the oracle only returns pairs (i, σ) for which one of the following three conditions holds

1. \bar{c} is good, $i = t$ and $\sigma = 0$ (if the conversation generated by M' is good and furthermore is not i -co-critical for any i 's then the oracle always answers this way);
2. \bar{c} is i -critical and $\sigma = 0$;
3. \bar{c} is i -co-critical and $\sigma = 1$.

⁵We stress that P'' is not necessarily the simulator-based prover of M'' .

Finally, the simulator halts outputting $(c_1, \dots, c_{i-1}, c_i \oplus \sigma)$. Note that i may be smaller than t , in which case M'' outputs a truncated (i -critical) conversation; otherwise, M'' outputs a non-truncated conversation. It remains to specify the oracle's answer distribution.

Let us start by considering two special cases. In the first case, the conversation generated by M' is i -critical, for some i , but is not j -co-critical for any $j < i$. In this case the oracle always answers $(i, 0)$ and consequently the simulator always outputs the i -bit long prefix. However, this prefix is still being output with too low probability. This will be corrected by the second case hereby described. In this ("second") case, the conversation \bar{c} generated by M' is good and i -co-critical for a single i . This means that the i -bit long prefix is given too much probability weight whereas the prefix obtained by complimenting the i^{th} bit gets too little weight. To correct this, the oracle outputs $(i, 1)$ with probability q and $(t, 0)$ otherwise, where q will be specified. What happens is that the M'' will output the " i -complimented prefix" with higher probability than with which it has appeared in M' . The value of q is determined as follows. Denote $p \stackrel{\text{def}}{=} \text{Prob}(V(c_1, \dots, c_{i-1}) = c_i \oplus 1)$ and $p' \stackrel{\text{def}}{=} \text{Prob}(V'(c_1, \dots, c_{i-1}) = c_i \oplus 1)$. Then, setting q so that $p = p' + (1 - p') \cdot q$ (i.e., $q = \frac{p-p'}{1-p'}$) allows the simulator to output the prefix $(c_1, \dots, c_{i-1}, c_i \oplus 1)$ with the right probability.

In the general case, the conversation generated by M' may be i -co-critical for many i 's as well as j -critical for some (*single*) j . In case it is j -critical, it can be i -co-critical only for $i < j$. Let us consider the sequence of indices, (i_1, \dots, i_l) , for which the generated conversation is critical or co-critical (i.e., the conversation is i_k -co-critical for all $k < l$ and is either i_l -critical or i_l -co-critical). We consider two cases. In both cases the q_k 's are defined as in the above example; namely, $q_k = \frac{p_k - p'_k}{1 - p'_k}$, where $p_k \stackrel{\text{def}}{=} \text{Prob}(V(c_1, \dots, c_{i_k-1}) = c_{i_k} \oplus 1)$ and $p'_k \stackrel{\text{def}}{=} \text{Prob}(V'(c_1, \dots, c_{i_k-1}) = c_{i_k} \oplus 1)$.

1. The generated conversation, $\bar{c} = (c_1, \dots, c_t)$, is i_k -co-critical for every $k < l$ and is i_l -critical. In this case, the distribution of the oracle answers is as follows. For every $k < l$, the pair $(i_k, 1)$ is returned with probability $(\prod_{j < k} (1 - q_j)) \cdot q_k$; whereas the pair $(i_l, 0)$ appears with probability $\prod_{j < l} (1 - q_j)$. We stress that no other pair appears in this distribution.
2. The generated conversation, $\bar{c} = (c_1, \dots, c_t)$, is i_k -co-critical for every $k \leq l$. In this case, the distribution of the oracle answers is as follows. For every $k \leq l$, the pair $(i_k, 1)$ is returned with probability $(\prod_{j < k} (1 - q_j)) \cdot q_k$; whereas the pair $(t, 0)$ appears with probability $\prod_{j \leq l} (1 - q_j)$. Again, no other pair appears in this distribution.

Claim 4.6

1. $[P'', V] \stackrel{s}{=} [P', V]$;
2. Each conversation of (P'', V) , be it a complete (P', V) -conversation or a truncated (i.e., critical) one, is output by M'' with probability that is at least a $(1 - \epsilon)^t > \frac{3}{4}$ fraction of the probability that it appears in $[P'', V]$.

proof: The weak conversations are negligible in the output distribution of (P', V) (see Claim 4.2). The only difference between $[P'', V]$ and $[P', V]$ originates from a different behavior of P'' on weak conversations, specifically P'' truncates them while P' does not. Yet, the distribution on the good conversations remains unchanged. Therefore the distribution of $[P'', V]$ is statistically close to the distribution of $[P', V]$, and we are done with part (1).

For part (2) we write again the probability that (P'', V) outputs \bar{c} as the product of the conditional probabilities of the t steps. Namely,

$$\prod_{i=1}^t \text{Prob}([P'', V]_{i+1} = h_i \circ c_{i+1} \mid [P'', V]_i = h_i)$$

where $h_i \stackrel{\text{def}}{=} (c_1, \dots, c_i)$. We do the same for the probability that M'' outputs a conversation \bar{c} . We will show by induction that each step of any conversation is produced by M'' with at least $(1 - \epsilon)$ the probability of the same step in the (P'', V) -interaction. Once we have shown this, we are done. Clearly this claim holds for the null prefix. To prove the induction step, we consider the two possibilities for the party making the $i + 1^{\text{st}}$ step.

$i + 1^{\text{st}}$ step is by the prover: Consider the conditional behavior of M'' given the history so far. We show that this behavior is identical to the behavior of P'' on the same partial history.

A delicate point to note here is that we may talk about the behavior of M'' on a prefix h_i only if this prefix appears with positive probability in the output distribution $[M'']_i$. However, by the induction hypothesis any prefix that is output by $[P'']_i$ appears with positive probability in $[M'']_i$.

The simulator M'' is defined by two modifications of M' . The first modification truncates i -th critical conversations after the i -th step, and the second modification compensates for the low weight given by the simulator to weak steps of the verifier. We note that the second modification concerns only the conditional behavior of the simulator on verifier steps and is thus irrelevant to the current case. On the other hand, the first modification exactly matches the modification applied on P' to get P'' . Specifically, P'' is identical to P' (which is the M' -based prover) except that it terminates immediately upon receiving a weak message of V with respect to the history so far.

To summarize, the conditional behavior of M'' in the prover steps and the conditional behavior of P'' are both based on the M' -based prover P' , and are both modified in exactly the same manner. Thus, their conditional behavior is exactly the same for any possible history.

$i + 1^{\text{st}}$ step is by the verifier: Again, we consider the conditional behavior of M'' given the history so far. Let us recall the second modification applied on M' to derive M'' . This modification changes the conditional probability of the verifier steps in the distribution of M' in order to add weight to steps having low probability in the

simulation. We note that this modification is made only in critical or co-critical steps of the verifier. Consider a history h_i which might appear in the interaction (P'', V) and a possible response β of V to h_i . Again, by the induction hypothesis, h_i has a positive probability to be output by the simulation M'' and therefore we may consider the behavior of M'' on this history h_i . There are three cases to be considered, corresponding to whether either β or $\beta \oplus 1$ or none is weak with respect to h_i .

We start with the simplest case in which neither β nor $\beta \oplus 1$ is weak (w.r.t. h_i). This case is dealt with exactly as the case that the $i + 1^{\text{st}}$ step is by the prover. Specifically, none of the modifications applied to M' is relevant here and the claim follows by the hypothesis that neither β nor $\beta \oplus 1$ is weak.

We now turn to the case in which β is weak (w.r.t. h_i). A weak message appears in the output of (P'', V) only if it is critical. Recall that given that M'' has produced the prefix h_i , it produces $h_i \circ \beta$ whenever M' produces the prefix $h_i \circ \beta$, and furthermore, with conditional probability q_{i+1} (as defined above), M'' produces the prefix $h_i \circ \beta$ also in case M' produces the prefix $h_i \circ (\beta \oplus 1)$.

Thus, using the above notations, we get

$$\begin{aligned}
\text{Prob}([M'']_{i+1} = h_i \circ \beta \mid [M'']_i = h_i) &= \text{Prob}([M']_{i+1} = h_i \circ \beta \mid [M'']_i = h_i) \\
&\quad + q_{i+1} \cdot \text{Prob}([M']_{i+1} = h_i \circ (\beta \oplus 1) \mid [M'']_i = h_i) \\
&= p'_{i+1} + q_{i+1} \cdot (1 - p'_{i+1}) \\
&= p'_{i+1} + \frac{p_{i+1} - p'_{i+1}}{1 - p'_{i+1}} \cdot (1 - p'_{i+1}) \\
&= \text{Prob}([P'']_{i+1} = h_i \circ \beta \mid [P'']_i = h_i)
\end{aligned}$$

Finally, we turn to the case in which $\beta \oplus 1$ is weak (w.r.t. h_i). Again, this means that β is co-critical in \bar{c} . Given that M'' has produced the prefix h_i , it produces $h_i \circ \beta$ only when M' produces the prefix $h_i \circ \beta$, and furthermore, M'' does so only with probability $1 - q_{i+1}$. Thus, noting that here p_{i+1} and p'_{i+1} refer to $h_i \circ (\beta \oplus 1)$, we get

$$\begin{aligned}
\text{Prob}([M'']_{i+1} = h_i \circ \beta \mid [M'']_i = h_i) &= (1 - q_{i+1}) \cdot \text{Prob}([M']_{i+1} = h_i \circ \beta \mid [M'']_i = h_i) \\
&= (1 - q_{i+1}) \cdot (1 - p'_{i+1}) \\
&= \left(1 - \frac{p_{i+1} - p'_{i+1}}{1 - p'_{i+1}}\right) \cdot (1 - p'_{i+1}) \\
&= \text{Prob}([P'']_{i+1} = h_i \circ \beta \mid [P'']_i = h_i)
\end{aligned}$$

This completes the proof of Claim 4.6. \square

Lowering the probability of some simulator outputs

The purpose of the last modification is to lower the probability that the simulator outputs a conversation, in case it outputs this conversation more frequently than it appears in (P'', V) . The modified simulator, denoted M''' , runs M'' to obtain a

conversation \bar{c} . (Note that M'' always produces output.) Using the further-augmented oracle, M''' outputs \bar{c} with probability

$$p_{\bar{c}} \stackrel{\text{def}}{=} \frac{3}{4} \cdot \frac{\text{Prob}([P'', V] = \bar{c})}{\text{Prob}([M'''] = \bar{c})} \leq 1$$

where the inequality holds due to part 2 of Claim 4.6.

Claim 4.7

1. M''' produces output with probability $\frac{3}{4}$;
2. The output distribution of M''' (i.e., in case it has output) is identical to the distribution $[P'', V]$.

proof: The probability that M''' produces an output is exactly:

$$\sum_{\bar{c}} \text{Prob}([M'''] = \bar{c}) \cdot p_{\bar{c}} = \frac{3}{4}$$

As for part (2), we note that the probability that a conversation \bar{c} is output by M''' is exactly $\frac{3}{4} \cdot \text{Prob}([P'', V] = \bar{c})$. Since the simulator halts with an output with probability exactly $\frac{3}{4}$, we get that given that M''' halts with an output, it outputs \bar{c} with probability exactly $\text{Prob}([P'', V] = \bar{c})$ and we are done. \square

An important point not explicitly addressed so far is whether all the modifications applied to the simulator preserve its ability to be implemented by a probabilistic polynomial-time with bounded access to an oracle. Clearly, this is the case with respect to M'' (at the expense of additional $1 + \log_2 t = O(\log n)$ oracle queries). Yet, regarding the last modification there is a subtle point which needs to be addressed. Specifically, we need to verify that the definition of M''' is implementable; namely, that M''' can (with help of an augmented oracle) “sieve” conversations with *exactly* the desired probability. Note that the method presented above (in the “technical remark”) may yield exponentially small deviation from the desired probability. This will get very close to a perfect simulation, but yet it will not achieve it.

To this end, we modify the “sieving process” suggested in the technical remark to deal with the specific case we have here. But first we modify P'' so that it makes its random choices (in case it has any) by flipping a polynomial number of unbiased coins. This rounding does change a bit the behavior of P'' , but the deviation can be made so small that the above assertions (specifically Claim 4.6) still hold.

Consider the specific sieving probability we need here. Namely: $p_{\bar{c}} = \frac{3}{4} \cdot \frac{a/b}{c/d}$, where $\frac{a}{b} = \text{Prob}([P'', V] = \bar{c})$ and $\frac{c}{d} = \text{Prob}([M'''] = \bar{c})$. A key observation is that c is the number of coin tosses which lead M'' to output \bar{c} (i.e., using the notation of the previous section, $c = |\Omega_{\bar{c}}|$). Observing that b is the size of probability space for $[P'', V]$ and using the above modification to P'' , we rewrite $p_{\bar{c}}$ as $\frac{3ad}{4b} \cdot \frac{1}{c} = \frac{e}{c2^f}$, where e and $f = \text{poly}(n)$ are some non-negative integers.

We now note, that the oracle can allow the simulator to sieve conversations with probability $\frac{e}{c}$ ($f = 0$), for any $0 \leq e \leq c$ in the following way. M''' sends to the oracle the random tape ω that it has tossed for M'' , and the oracle sieves only e out of the possible c random tapes which lead M'' to output \bar{c} . The general case of $p_{\bar{c}} = \frac{e}{c2^f}$ is dealt by writing $p_{\bar{c}} = \frac{q}{c} + \frac{r}{c2^f}$, where $q = \lfloor e/2^f \rfloor$ and $r = e - q2^f < 2^f$. To implement this sieve, M''' supplies the oracle with a uniformly chosen f -bit long string (in addition to ω). The oracle sieves out q random-tapes (of M'') as before, and uses the extra bits in order to decide on the sieve in case ω equals a specific (different) random-tape.

Combining Claims 4.1, 4.6 (part 1), and 4.7, we conclude that (P'', V) is an interactive proof system of *perfect* knowledge complexity $k(n) + O(\log n)$ for L . This completes the proof of Theorem 2. ■

5 Concluding Remarks

We consider our main result as a very first step towards a classification of languages according to the knowledge complexity of their interactive proof systems. Indeed there is much to be known. Below we first mention two questions which do not seem too ambitious. The first is to try to provide evidence that NP-complete languages cannot be proven within low (say logarithmic or even constant) knowledge complexity. A possible avenue for proving this conjecture is to show that languages having logarithmic knowledge complexity are in co-AM , rather than in $\mathcal{BPP}^{\text{NP}}$ (see [BHZ-87]). The second suggestion is to try to provide indications that there are languages in \mathcal{PSPACE} which do not have interactive proofs of linear (rather than logarithmic) knowledge complexity. The reader can easily envision more moderate and more ambitious challenges in this direction.

Another interesting question is whether all levels greater than zero of the knowledge-complexity hierarchy contain strictly more languages than previous levels, or if some partial collapse occurs. For example, it is open whether constant or even logarithmic knowledge complexity classes do not collapse to the zero level.

Regarding our transformation of statistical knowledge complexity into perfect knowledge complexity (i.e., Theorem 2), a few interesting questions arise. Firstly, can the cost of the transformation be reduced to below $O(\log n)$ bits of knowledge? A result for the special case of statistical zero-knowledge will be almost as interesting. Secondly, can one present an analogous transformation that preserves *one-sided error probability* of the interactive proof? (Note that our transformation introduces a negligible error probability into the completeness condition.) Finally, can one present an analogous transformation that applies to knowledge complexity *with respect to arbitrary verifiers*? (Our transformation applies only to knowledge complexity *with respect to the honest verifier*.)

A APPENDIX: Proof of a Technical claim

Let us prove the technical claim used in the proof of Lemma 3.1.

Claim A.1 *Let $x_i, y_i, 1 \leq i \leq n$ be non-negative reals, let $X = \sum_i x_i$ and $Y = \sum_i y_i$. Then the minimum of*

$$\sum_i \frac{x_i^2}{y_i}$$

is obtained when $\frac{x_i}{y_i} = \frac{X}{Y}$ for all $1 \leq i \leq n$ and is thus equal to $\frac{X^2}{Y}$.

Proof: Using Lagrange multipliers, we would like to minimize the expression

$$\sum_i \frac{x_i^2}{y_i} + \Lambda_1 \cdot \left(X - \sum_i x_i \right) + \Lambda_2 \cdot \left(\sum_i y_i - Y \right)$$

Deriving according to x_k ($1 \leq k \leq n$) and equating to 0, we get:

$$\forall 1 \leq k \leq n \quad 2 \cdot x_k = \Lambda_1 \cdot y_k$$

The same operation for $y_k, 1 \leq k \leq n$, yields:

$$\forall 1 \leq k \leq n \quad x_k = \sqrt{\Lambda_2} \cdot y_k$$

Summing over k , we get:

$$\frac{X}{Y} = \frac{\Lambda_1}{2} = \sqrt{\Lambda_2}$$

and thus, the optimum is achieved when $\frac{x_i}{y_i} = \frac{X}{Y}$ for all $1 \leq i \leq n$.

It remains to see that the optimum is indeed a minimum. To this end, we consider the second derivation. Deriving by x_k , we get $2/y_k$ and deriving by y_k we get $\frac{x_k^2}{y_k^3}$. Both are positive for all $1 \leq k \leq n$ since all x_k and y_k are (strictly) positive at the optimum point. Thus, the optimum is indeed a minimum. \square

B APPENDIX: A Flaw in [F-89]

In [F-89], Fortnow presents a constructive method for proving that $\mathcal{SZK} \stackrel{\text{def}}{=} \mathcal{SKC}(0)$ is contained in $\text{co-}\mathcal{AM}$. Given an interactive proof (P, V) for a language L and a (statistical) zero-knowledge simulator M (for the honest verifier V), he constructs a two-round protocol (P', V') (for \bar{L}). This protocol is claimed to constitute an interactive proof system for \bar{L} . This claim, as we are going to show, is wrong. Yet, the result $\mathcal{SZK} \subseteq \text{co-}\mathcal{AM}$ does hold, since the work of Aiello and Hastad contains the necessary refinements which enable to present a modified AM-protocol for \bar{L} (see [AH-87, H-94]). Furthermore, Fortnow's basic approach is valid, and indeed it was used in subsequent works (e.g., [AH-87, BMO-90, Ost-91, BP-92, OW-93]).

Fortnow's basic approach starts with the observation that the simulator M must behave differently on $x \in L$ and $x \notin L$. Clearly, the difference cannot be recognized in polynomial-time, unless $L \in \mathcal{BPP}$. Yet, stronger recognition devices, such as interactive proofs should be able to tell the difference. Fortnow suggests a characterization of the simulator's behavior on $x \in L$ and uses this characterization in his protocol for \bar{L} , yet this characterization is wrong. Aiello and Hastad present a refinement of Fortnow's characterization [AH-87], their characterization is correct and can be used to show that $\mathcal{SZK} \subseteq \mathcal{AM}$ (which is the goal of their paper) as well as $\mathcal{SZK} \subseteq \text{co-}\mathcal{AM}$.

Fortnow's characterization

Given an interactive proof (P, V) for L and a simulator M , and fixing a common input $x \in \{0, 1\}^*$, the following sets are defined. Let us denote by t the number of random bits that the verifier V uses on input x , and by q the number of random bits used by the simulator M . For every conversation prefix, h , we consider the set of the verifier's coin tosses which are consistent with h (the conversation so far). We denote this set by R_1^h . Namely, for $h = (\alpha_1, \beta_1, \dots, \alpha_i, \beta_i)$ (or $h = (\alpha_1, \beta_1, \dots, \alpha_i, \beta_i, \alpha_{i+1})$), $r \in R_1^h$ iff $V(x, r, \alpha_1, \dots, \alpha_j) = \beta_j$ for every $j \leq i$, where $V(x, r, \bar{\alpha})$ denotes the message sent by V on input x random-tape r and prover message-sequence $\bar{\alpha}$. The set R_1^h depends only on the verifier V . Next, we consider sets R_2^h which are subsets of the corresponding R_1^h 's. Specifically, they contain only r 's that can appear with h in an accepting conversation output by the simulator M . Namely, $r \in R_2^h$ iff $r \in R_1^h$ and there exists $\omega \in \{0, 1\}^q$ so that $M(x, \omega)$ is an accepting conversation with prefix h . (Here $M(x, \omega)$ denotes the conversation output by M on input x and simulator-random-tape ω .)

Motivation: For simplicity, suppose that the simulation is perfect (i.e., M witnesses that (P, V) is *perfect* zero-knowledge) and that (P, V) has one sided error (i.e., "perfect completeness"). Then, for every $x \in L$ and every possible h , we must have $R_2^h = R_1^h$ (otherwise the simulation is not perfect). However, if $x \notin L$ then there must exist h 's so that R_2^h is much smaller than R_1^h . Otherwise the simulator-based prover (for M) will always convince V to accept x , thus violating the soundness condition of (P, V) . The problem with the above dichotomy is that it is "too existential" and

thus it is not clear how to use it. Instead Fortnow claimed the dichotomy which is more quantitative.

A False Characterization: Let $\text{pref}(\bar{c})$ denote the set of all message-subsequences in the conversation \bar{c} .

- if $x \in L$ then

$$\text{Prob}_\omega(\forall h \in \text{pref}(M(x, \omega)) \quad |R_2^h| \approx_1 |R_1^h|) > \frac{3}{4}$$

- if $x \notin L$ then

$$\text{Prob}_\omega(\forall h \in \text{pref}(M(x, \omega)) \quad |R_2^h| \approx_2 |R_1^h|) < \frac{1}{4}$$

where the probability (in both cases) is taken uniformly over $\omega \in \{0, 1\}^q$. We did not specify what is meant by \approx_i . One may substitute \approx_1 by $\geq \frac{1}{2}$, and \approx_2 by $\leq \frac{1}{4}$. The gap between the two is needed for the approximate lower/upper bound protocols.

A Counterexample

The mistake is in the second item of the characterization. The false argument given in [F-89] confuses between the probability distribution of conversations output by the simulator and the probability distribution of the conversations between a simulator-based prover (denote P^*) and the verifier. These distributions are not necessarily the same (note that we are in case $x \notin L$). Consequently, the probability that “good” conversations (i.e., conversations for which $|R_2| \approx |R_1|$ for all prefixes) occur in the (P^*, V) interaction is not the same as the probability that the simulator outputs “good” conversations. This point is ignored in [F-89] and leads there to the false conclusion that the characterization holds. Bellow, we present an interactive proof (P, V) and a (perfect) zero-knowledge simulator for which the characterization fails.

The interactive proof that we present is for the empty language Φ . This interactive proof is perfect zero knowledge for the trivial reason that the requirement is vacuous. Yet, we present a simulator for this interactive proof which, for every $x \in \{0, 1\}^* = \bar{\Phi}$, outputs “good” conversation with probability close to 1. Thus, the characterization fails.

The interactive proof (from the verifier’s point of view – input $x \in \{0, 1\}^n$):

- The verifier uniformly selects $\alpha \in \{0, 1\}^n$ and sends α to the prover.
- The verifier waits for the prover’s message $\beta \in \{0, 1\}^n$.
- Next, the verifier uniformly selects $\gamma \in \{0, 1\}^n$ and sends γ to the prover.
- The verifier accepts iff either $\alpha = 0^n$ or $\beta = \gamma$.

Regardless of the prover’s strategy, the verifier accepts each $x \in \{0, 1\}^n$ with negligible probability; specifically $2^{-n} + (1 - 2^{-n}) \cdot 2^{-n}$. Thus, the above protocol indeed constitutes an interactive proof for the empty language Φ .

The simulator operates as follows (on input $x \in \{0, 1\}^n$):

- With probability $1 - \epsilon$, the simulator M outputs a conversation uniformly distributed in $0^n \times \{0, 1\}^{2n}$. (ϵ is negligible, say $\epsilon = 2^{-n}$)
- With probability ϵ , the simulator M outputs a conversation uniformly distributed in $(\{0, 1\}^n - 0^n) \times \{0, 1\}^{2n}$.

Claim: In contradiction to the characterization, for every $x \in \{0, 1\}^* = \overline{\Phi}$,

$$\text{Prob}_\omega(\forall h \in \text{pref}(M(x, \omega)) \mid R_2^h \mid = \mid R_1^h \mid) \geq 1 - \epsilon$$

Proof: It suffices to show that every conversation of the form $0^n \beta \gamma$ satisfies $R_2 = R_1$ for all its prefixes. First observe that $R_1^\lambda = \{0, 1\}^{2n} = R_2^\lambda$, since for every $\alpha \gamma \in \{0, 1\}^{2n}$ the simulator outputs the accepting conversation $\alpha \gamma \gamma$ with non-zero probability. Similarly, $R_1^{0^n} = 0^n \{0, 1\}^n = R_2^{0^n}$. Next, for every $\beta \in \{0, 1\}^n$, we have $R_1^{0^n \beta} = 0^n \{0, 1\}^n = R_2^{0^n \beta}$, since for every $\gamma \in \{0, 1\}^n$ the simulator outputs the accepting conversation $0^n \beta \gamma$ with non-zero probability. (Here we use the fact that the verifier always accepts when $\alpha = 0^n$.) Similarly, $R_1^{0^n \beta \gamma} = 0^n \gamma = R_2^{0^n \beta \gamma}$. \square

Conclusion

The source of trouble is that the definition of the sets R_2^h 's does not take into account the probability weight assigned by the simulator to ω 's that witness the assertion "the simulator outputs an accepting conversation that starts with h ". Indeed, this is exactly the nature of the refinement suggested by Aiello and Hastad [AH-87].
